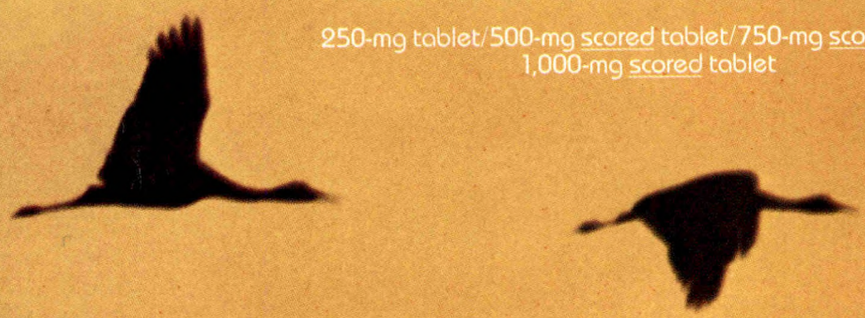
Return to a natural cardiac rhythm

SUSTAINED RELEASE Procan® SR (PROCAINAMIDE HYDROCHLORIDE TABLETS)

250-mg tablet/500-mg scored tablet/750-mg scored tablet
1,000-mg scored tablet



Now available
"**UNIT OF USE**"
A full month's supply
(120 tablets) for each
dosage strength

Enhances the value of oral procainamide for selected cardiac dysrhythmias

With modern sustained-release Procan SR, short duration of effect no longer impedes the usefulness of procainamide for maintenance therapy. A standard medication now assumes greater importance, both in terms of convenience and patient compliance.

- Administered half as often as conventional oral procainamide
- Wide versatility in cardiac conditions
- Can be used concomitantly with digoxin
- Ideal maintenance therapy

Procan SR... the original sustained-release oral procainamide

Introducing the new HP Series 100 Imaging System. Designed to fit your office. And your budget.

It's a smaller unit. With a lower price. But the quality is pure HP. Performance. Reliability. Upgradeability.

Through advanced technology, we've been able to integrate the attributes that have made our phased array system the leader in cardiac imaging into the new HP Series 100.

Superior image quality. 2-D, M-mode, PW and CW Doppler capabilities. Excellent resolution over a wide range of cardiac imaging applications in patients ranging from neonates to adults. Plus added features that make the HP Series 100 ideal for the office. A large 12″ monitor for easy viewing. A compact, ergonomic design that puts simple, easy-to-use controls at your fingertips.

Portability. Flexibility. We considered these, too. That's why the HP Series 100 has been designed to be used on tabletop or cart.

Advanced technology is just the beginning.

Add HP training, service and our nationwide support network, and the picture is clear. The HP Series 100 just may be the best surprise you've seen all year.

For further information, call **1-800-637-3747**. (In MA, 1-617-687-1501, ext. 2475.) Or write: Inquiries Manager, Hewlett-Packard, Dept. MPG, 3000 Minuteman Road, Andover, MA 01810.

THICK OR THIN SKINNED... THEY RESPOND TO DEPONIT®

System-controlled... not skin-controlled[1-4]

That means variations in thickness of the stratum corneum have no significant effect on skin permeation. Deponit® NTG-FILM is gradient-charged™* to provide controlled release of free drug at the skin surface—for uniform transdermal bioavailability. There is no premature NTG dumping.

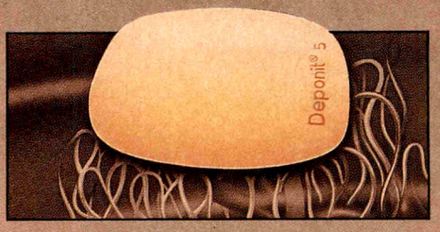
Proven in hundreds of U.S. patients

In studies of over 500 anginal† patients treated with Deponit, the large majority showed a reduced frequency of anginal attacks and improved ability to perform everyday activities such as walking, stair climbing and sex. And Deponit efficacy was sustained during these routine activities.[5]

THE FIRST GRADIENT-CHARGED™ NTG-FILM FOR ANGINA† PROPHYLAXIS

Deponit®

(nitroglycerin transdermal delivery system) 5 mg/24 hours 10 mg/24 hours



THROUGH THICK OR THIN

- System-controlled, not skin-controlled
- Minimal variations in absorption
- No premature release of NTG
- Designed for superior patient acceptance
- Once-a-day dosing, 24-hour delivery
- International record of success

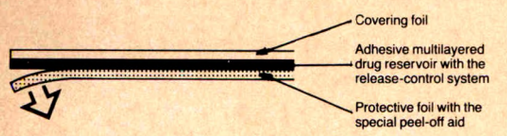
WYETH AYERST™

Wyeth-Ayerst®
Deponit®
(nitroglycerin transdermal delivery system)
5 mg/24 hours, 10 mg/24 hours

Description
Deponit® is a unique nitroglycerin-containing transdermal delivery system. A multilayered self-adhesive film, the system contains nitroglycerin in a matrix composed of lactose, plasticizer, medical adhesive, polyisobutylene, and aluminized plastic for controlled release of the active agent through the skin into the systemic circulation. For the 24 hours during which the system is applied to the intact skin, its technology is intended to deliver an accurate dosage with no premature release of the nitroglycerin or undesired accumulation on the skin. Nitroglycerin (glyceryl trinitrate) is a vasodilator for the relief and prevention of anginal attacks.
Deponit® is available in two strengths which release either 5 mg or 10 mg of nitroglycerin during a 24-hour period. The 5 mg/24 hr system has a 16 cm^2 releasing surface and contains 16 mg nitroglycerin. The 10 mg/24 hr system has a 32 cm^2 releasing surface and contains 32 mg nitroglycerin.
The Deponit® system is approximately 0.3 mm thick, insoluble in water, and, as illustrated below, consists of two main elements:
1. A flexible, flesh-colored waterproof covering foil.
2. A multilayered adhesive film that constitutes simultaneously the drug reservoir and the release-control system.



The system is protected by an aluminum foil which has a patented S-shaped opening to facilitate its removal prior to use of the system.

Clinical Pharmacology
When the Deponit® system is applied to the skin, nitroglycerin is continuously released for absorption directly into the systemic circulation. Thus, active drug reaches the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth-muscle relaxant with vascular effects manifested predominantly by venous dilatation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption, secondary to vascular smooth-muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.
In a bioavailability study using healthy volunteers,[1] transdermal absorption of nitroglycerin from the Deponit® system achieved steady-state venous plasma levels and maintained these levels for 24 hours. Detectable plasma levels were attained within 30 minutes after application of the system and were still detectable 30 minutes after removal of the system.
The amount of nitroglycerin released (5 mg/24 hr or 10 mg/24 hr) represents the mean release rate of nitroglycerin from the system as determined from healthy volunteers, and hence, the amount potentially available through the skin. Absorption will vary among individuals. Precise definition of "therapeutic plasma level" is not known at this time.

Indications and Usage
This drug product has been conditionally approved by the FDA for the prevention and treatment of angina pectoris due to coronary artery disease. The conditional approval reflects a determination that the drug may be marketed while further investigation of its effectiveness is undertaken. A final evaluation of the effectiveness of the product will be announced by the FDA.

Contraindications
Nitroglycerin is contraindicated in patients known to be intolerant of organic nitrate drugs and in patients with marked anemia.

Warnings
In patients with acute myocardial infarction or congestive heart failure, nitroglycerin should be used under careful clinical and/or hemodynamic monitoring.
In terminating treatment of patients with angina, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent the sudden withdrawal reactions which are characteristic of vasodilators in the nitroglycerin class.
Transdermal nitroglycerin systems should be removed before attempting defibrillation or cardioversion because of the potential for altered electrical conductivity which may enhance the possibility of arcing, a phenomenon associated with the use of defibrillators.

Precautions
Symptoms of hypotension, such as faintness, weakness, or dizziness, particularly orthostatic hypotension, may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.
Deponit® is not intended for use in treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitrates may be necessary.
PREGNANCY
Pregnancy Category C. Animal reproduction studies have not been conducted with nitroglycerin. It is not known whether nitroglycerin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Nitroglycerin should be given to a pregnant woman only if clearly needed.
NURSING MOTHERS
It is not known whether nitroglycerin is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when the preparation is administered to a nursing woman.

Adverse Reactions
Transient headache is the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Deponit® therapy is continued. When such headaches are unresponsive to treatment, the dosage should be reduced or use of the product discontinued.
Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis these symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist, the Deponit® dose should be reduced or use of the product discontinued.

Dosage and Administration
Deponit® can be applied as a single system or as multiples, depending upon the clinical requirements. Dosage should be titrated to achieve the optimal therapeutic effect by monitoring clinical response, side effects, heart rate, and the effect of therapy upon blood pressure.
Deponit® should be removed from the single-unit package just prior to use. The protective aluminum precut S-shaped foil is removed according to the "Patient Instructions," and the system is applied with a firm pressure on a convenient skin site, preferably on the chest, inner side of the upper arm, or shoulders. Deponit® should not be applied to the distal parts of extremities.
Each system is designed to remain in place for 24 hours; however, the treatment site should be changed daily to minimize skin irritation and should be intact, clean, and dry. If necessary, hair may be removed by clipping.
Therapy should be initiated with application of a single Deponit® system, delivering 5 mg every 24 hours. Response in terms of satisfactory control of anginal symptoms without adverse effects should be evaluated to determine the optimal dose. Some patients may require adjustment of dosage to provide a better clinical response. This can be achieved by removing the system delivering 5 mg/24 hours, and applying a larger system delivering 10 mg/24 hours or a multiple of either system, depending on the dose required to achieve the desired effect.
After 24 hours, the system should be removed and discarded. Because no adhesive residue remains on the skin, there is no need to use a solvent.

Storage Conditions
Store at room temperature not above 25°C (77°F). Do not refrigerate.

Patient Instructions for Application
A leaflet describing use of Deponit® is provided with each package.

How Supplied
Deponit® (nitroglycerin transdermal delivery system), Wyeth-Ayerst®, is packaged in cartons containing unit doses of 30 flesh-colored systems on aluminum backings. See table below.

Nitroglycerin released *in vivo*	Total drug content/ system	System size	Carton size
5 mg/24 hrs	16 mg	16 cm^2	30 Systems **(NDC 0008-4195-01)**
10 mg/24 hrs	32 mg	32 cm^2	30 Systems **(NDC 0008-4196-01)**

Caution: Federal law prohibits dispensing without prescription.

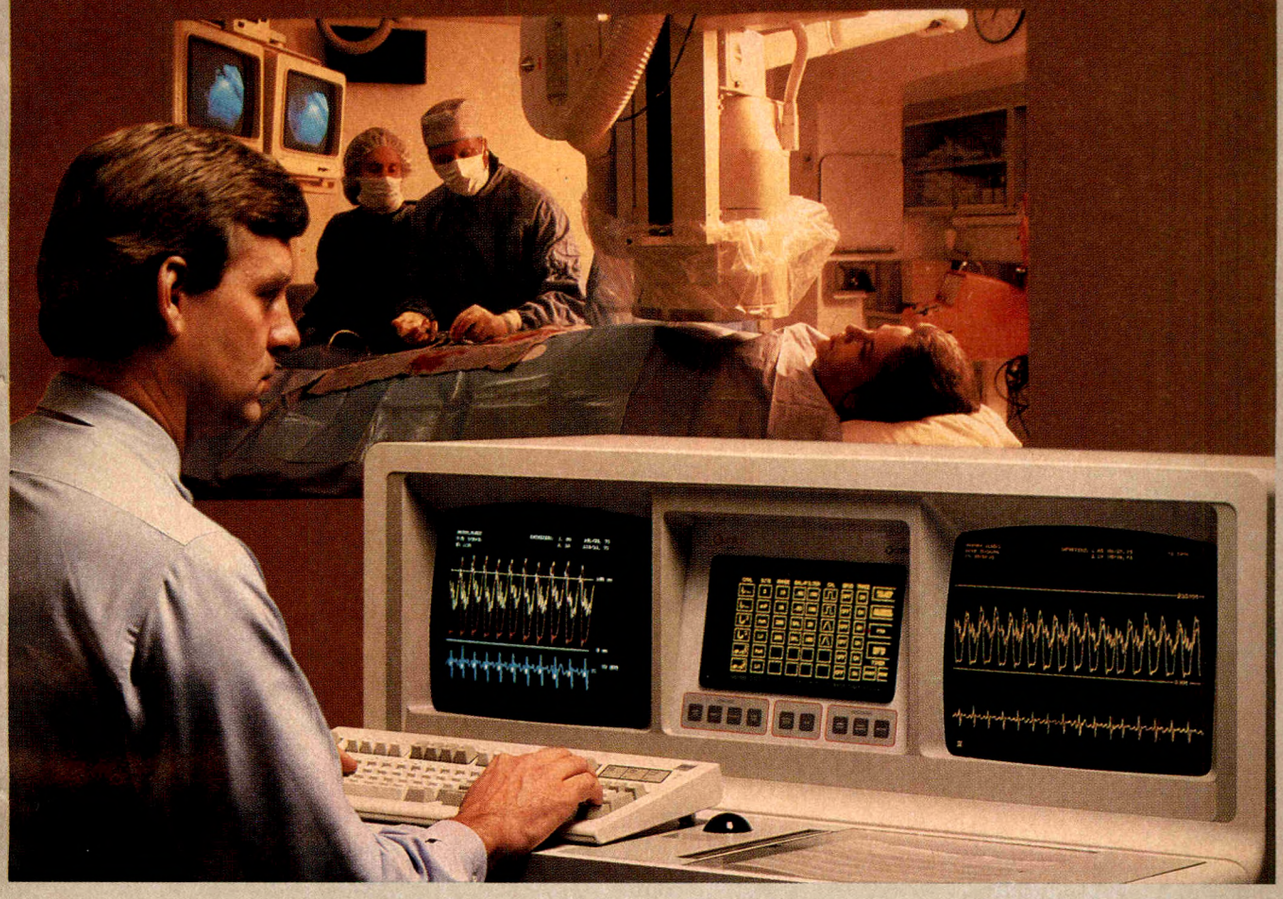
Q-cath™ The Problem Solver



The Cath Lab Recording System Designed to Make Data Collection and Analysis Easier, More Accurate, and Less Costly

Before designing Q-cath, we asked cardiologists and cath lab technicians what features were most important. What the current systems lacked. We conducted surveys, focus panels, and in-depth interviews with experts. We listened. And then we created **Q-cath—the computerized cath lab recording system.**

We tackled the tough problems:

- PROBLEM: Poor signal quality and waveform drift prevent quick and accurate data analysis.
  SOLUTION: A new approach to signal conditioning minimizes baseline drift, improves overall signal fidelity, and simplifies transducer calibration.
- PROBLEM: Bulky signal conditioning equipment that is difficult to set up and adjust.
  SOLUTION: A single, compact signal conditioning system with all monitoring and controls centrally located on the main console—making setup and balancing of channels quick and easy.
- PROBLEM: Chart recorders are bulky, inconvenient to use, and chart paper is expensive.
  SOLUTION: A compact, high-resolution chart recorder that prints both waveform graphics and text. Non-fade thermal paper provides cost savings of up to 80% over expensive silver paper.
- PROBLEM: Limited report formatting and generation capability.
  SOLUTION: A simple formatting procedure for customizing final reports so they contain only the information you want.

Those are a few examples. There's a lot more to Q-cath such as—inventory control and lab management systems, software for customizing your programs, angiography and angioplasty reporting systems, and the optional remote analysis work station and ventriculography analysis system.

But we can't tell you the whole story in one ad. So call us for more information:

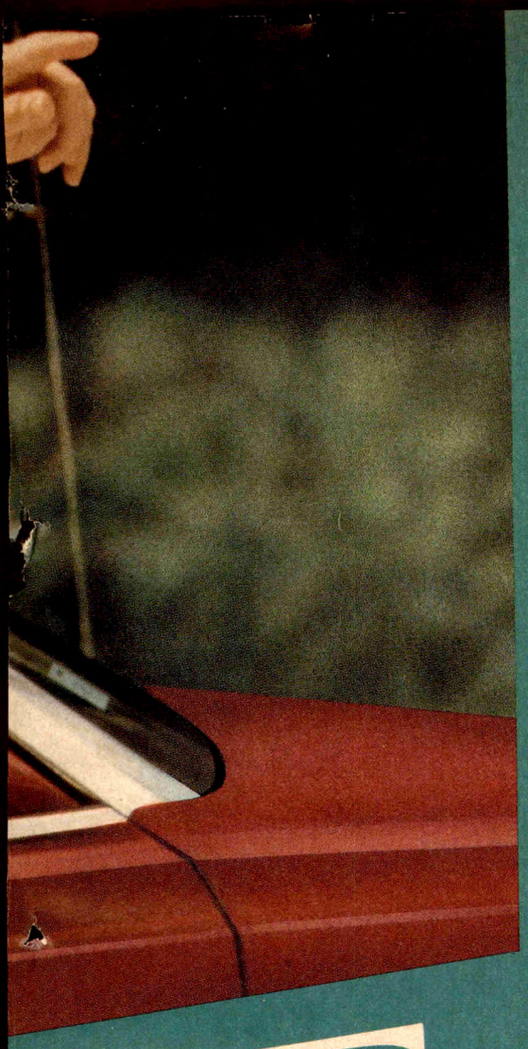
IN HYPERTENSION*

QUALITY

***CAPOTEN® (captopril tablets) may be used as initial therapy only for patients with normal renal function in whom the risk of neutropenia/agranulocytosis is relatively low (1 out of over 8,600 in clinical trials). Use special precautions in patients with impaired renal function, collagen vascular disorders, or those exposed to other drugs known to affect the white cells or immune response. Evaluation of hypertensives should always include assessment of renal function. Overall, the most frequently occurring adverse reactions associated with CAPOTEN are skin rash and taste alteration; both effects are generally mild, reversible, or self-limited. See INDICATIONS AND USAGE, WARNINGS, and ADVERSE REACTIONS in the brief summary on the adjacent page.**

---

1. Croog SH, Levine S, Testa MA, et al: The effects of antihypertensive therapy on the quality of life. N Engl J Med 314(26):1657-1664, 1986.
2. Data on file, University of Connecticut.



SQUIBB

Means a feeling of well-being.

Well-being—a feeling difficult to describe when it's present; easy to spot when it's gone. CAPOTEN improved hypertensive patients' sense of general well-being.[1] CAPOTEN had a positive effect on patients' vitality and general health. In fact, all measures of well-being studied showed a trend toward improvement.[2]

These data are based on a multicenter, randomized, 24-week study of 626 mild-to-moderate hypertensive male patients with normal renal function, 181 of whom received captopril.

CAPOTEN—things are looking up for patients who need to keep their blood pressure down.

OF LIFE

THE

CAPOTEN®

(captopril tablets)

DIFFERENCE

QUALITY OF LIFE THE CAPOTEN® (captopril tablets) DIFFERENCE

CAPOTEN® TABLETS
Captopril Tablets

INDICATIONS: Hypertension – CAPOTEN (captopril) is indicated for the treatment of hypertension. Consideration should be given to the risk of neutropenia/agranulocytosis (see WARNINGS). CAPOTEN may be used as initial therapy for patients with normal renal function, in whom the risk is relatively low. In patients with impaired renal function, particularly those with collagen vascular disease, captopril should be reserved for those who have either developed unacceptable side effects on other drugs, or have failed to respond satisfactorily to drug combinations. CAPOTEN is effective alone and in combination with other antihypertensive agents, especially thiazide-type diuretics.

Heart Failure: CAPOTEN (captopril) is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.

CONTRAINDICATIONS: CAPOTEN is contraindicated in patients who are hypersensitive to this product.

WARNINGS: Neutropenia/Agranulocytosis – Neutropenia ($< 1000/mm^3$) with myeloid hypoplasia has resulted from use of captopril. About half of the neutropenic patients developed systemic or oral cavity infections or other features of the syndrome of agranulocytosis. The risk of neutropenia is dependent on the clinical status of the patient:

In clinical trials in patients with hypertension who have normal renal function (serum creatinine less than 1.6 mg/dL and no collagen vascular disease), neutropenia has been seen in one patient out of over 8,600 exposed. In patients with some degree of renal failure (serum creatinine at least 1.6 mg/dL) but no collagen vascular disease, the risk in clinical trials was about 1 per 500. Doses were relatively high in these patients, particularly in view of their diminished renal function. In patients with collagen vascular diseases (e.g., systemic lupus erythematosus, scleroderma) and impaired renal function, neutropenia occurred in 3.7% of patients in clinical trials. While none of the over 750 patients in formal clinical trials of heart failure developed neutropenia, it has occurred during the subsequent clinical experience. Of reported cases, about half had serum creatinine $\geq$ 1.6 mg/dL and more than 75% received procainamide. In heart failure, it appears that the same risk factors for neutropenia are present.

Neutropenia has appeared usually within 3 months after starting therapy, associated with myeloid hypoplasia and frequently accompanied by erythroid hypoplasia and decreased numbers of megakaryocytes (e.g., hypoplastic bone marrow and pancytopenia); anemia and thrombocytopenia were sometimes seen. Neutrophils generally returned to normal in about 2 weeks after captopril was discontinued, and serious infections were limited to clinically complex patients. About 13% of the cases of neutropenia have ended fatally, but almost all fatalities were in patients with serious illness, having collagen vascular disease, renal failure, heart failure or immunosuppressant therapy, or a combination of these complicating factors. **Evaluation of the hypertensive or heart failure patient should always include assessment of renal function.** If captopril is used in patients with impaired renal function, white blood cell and differential counts should be evaluated prior to starting treatment and at approximately 2-week intervals for about 3 months, then periodically. In patients with collagen vascular disease or who are exposed to other drugs known to affect the white cells or immune response, particularly when there is impaired renal function, captopril should be used only after an assessment of benefit and risk, and then with caution. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat, fever). If infection is suspected, perform white cell counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count $< 1000/mm^3$) withdraw captopril and closely follow the patient's course.

Proteinuria: Total urinary proteins >1 g per day were seen in about 0.7% of patients on captopril. About 90% of affected patients had evidence of prior renal disease or received high doses (>150 mg/day), or both. The nephrotic syndrome occurred in about one-fifth of proteinuric patients. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued. The BUN and creatinine were seldom altered in proteinuric patients. Since most cases of proteinuria occurred by the 8th month of therapy with captopril, patients with prior renal disease or those receiving captopril at doses >150 mg per day, should have urinary protein estimates (dip-stick on 1st morning urine) before therapy, and periodically thereafter.

Hypotension: Excessive hypotension was rarely seen in hypertensive patients but is a possibility in severely salt/volume-depleted persons such as those treated vigorously with diuretics (see PRECAUTIONS [Drug Interactions]). In heart failure, where the blood pressure was either normal or low, transient decreases in mean blood pressure >20% were recorded in about half of the patients. This transient hypotension may occur after any of the first several doses and is usually well tolerated, although rarely it has been associated with arrhythmia or conduction defects. A starting dose of 6.25 or 12.5 mg tid may minimize the hypotensive effect. Patients should be followed closely for the first 2 weeks of treatment and whenever the dose of captopril and/or diuretic is increased.

BECAUSE OF THE POTENTIAL FALL IN BLOOD PRESSURE IN THESE PATIENTS, THERAPY SHOULD BE STARTED UNDER VERY CLOSE MEDICAL SUPERVISION.

PRECAUTIONS: General: *Impaired Renal Function* – Hypertension – Some hypertensive patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible. Heart Failure – About 20% of patients develop stable elevations of BUN and serum creatinine >20% above normal or baseline upon long-term treatment. Less than 5% of patients, generally with severe preexisting renal disease, required discontinuation due to progressively increasing creatinine. See DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]. *Valvular Stenosis* – A theoretical concern, for risk of decreased coronary perfusion, has been noted regarding vasodilator treatment in patients with aortic stenosis due to decreased afterload reduction. *Surgery/Anesthesia* – If hypotension occurs during surgery or anesthesia, and is considered due to the effects of captopril, it is correctable by volume expansion.

Drug Interactions: *Hypotension – Patients on Diuretic Therapy* – Precipitous reduction of blood pressure may occasionally occur within the 1st hour after administration of the initial of captopril dose in patients on diuretics, especially those recently placed on diuretics, and those on severe dietary salt restriction or dialysis. This possibility can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy or by initiating therapy with small doses (6.25 or 12.5 mg). Alternatively, provide medical supervision for at least 1 hour after the initial dose.

Agents Having Vasodilator Activity – In heart failure patients, vasodilators should be administered with caution.

Agents Causing Renin Release – Captopril's effect will be augmented by antihypertensive agents that cause renin release.

Agents Affecting Sympathetic Activity – The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

Agents Increasing Serum Potassium – Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium. Use potassium-containing salt substitutes with caution.

Inhibitors of Endogenous Prostaglandin Synthesis – Indomethacin and other nonsteroidal anti-inflammatory agents may reduce the antihypertensive effect of captopril, especially in low renin hypertension.

Drug/Laboratory Test Interaction: Captopril may cause a false-positive urine test for acetone.

Carcinogenesis, Mutagenesis and Impairment of Fertility: Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential. Studies in rats have revealed no impairment of fertility.

Pregnancy: Category C: There are no adequate and well-controlled studies in pregnant women. Embryocidal effects and craniofacial malformations were observed in rabbits. Therefore, captopril should be used during pregnancy, or for patients likely to become pregnant, only if the potential benefit outweighs the potential risk to the fetus. Captopril crosses the human placenta.

Nursing Mothers: Captopril is secreted in human milk. Exercise caution when administering captopril to a nursing woman, and, in general, nursing should be interrupted.

Pediatric Use: Safety and effectiveness in children have not been established although there is limited experience with use of captopril in children from 2 months to 15 years of age. Dosage, on a weight basis, was comparable to that used in adults. CAPOTEN (captopril) should be used in children only if other measures for controlling blood pressure have not been effective.

ADVERSE REACTIONS: Reported incidences are based on clinical trials involving approximately 7000 patients.

Renal – About 1 of 100 patients developed proteinuria (see WARNINGS). Renal insufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patients.

Hematologic – Neutropenia/agranulocytosis has occurred (see WARNINGS). Anemia, thrombocytopenia, and pancytopenia have been reported.

Dermatologic – Rash, (usually maculopapular, rarely urticarial), often with pruritus, and sometimes with fever and eosinophilia, in about 4 to 7 of 100 patients (depending on renal status and dose), usually during the 1st 4 weeks of therapy. Pruritus, without rash, in about 2 of 100 patients. A reversible associated pemphigoid-like lesion, and photosensitivity, have also been reported. Angioedema of the face, mucous membranes of the mouth, or of the extremities in about 1 of 1000 patients – reversible on discontinuance of captopril therapy. One case of laryngeal edema has been reported. Flushing or pallor in 2 to 5 of 1000 patients.

Cardiovascular – Hypotension may occur; see WARNINGS and PRECAUTIONS [Drug Interactions] for discussion of hypotension on initiation of captopril therapy. Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocardial infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 1000 patients.

Dysgeusia – Approximately 2 to 4 (depending on renal status and dose) of 100 patients developed a diminution or loss of taste perception; taste impairment is reversible and usually self-limited even with continued drug use (2 to 3 months). Gastric irritation, abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulcers, peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, cough, alopecia, paresthesias reported in about 0.5 to 2% of patients but did not appear at increased frequency compared to placebo or other treatments used in controlled trials.

Altered Laboratory Findings: Elevations of liver enzymes in a few patients although no causal relationship has been established. Rarely cholestatic jaundice, and hepatocellular injury with or without secondary cholestasis, have been reported. A transient elevation of BUN and serum creatinine may occur, especially in volume-depleted or renovascular hypertension patients. In instances of rapid reduction of longstanding or severely elevated blood pressure, the glomerular filtration rate may decrease transiently, also resulting in transient rises in serum creatinine and BUN. Small increases in serum potassium concentration frequently occur, especially in patients with renal impairment (see PRECAUTIONS).

OVERDOSAGE: Primary concern is correction of hypotension. Volume expansion with an I.V. infusion of normal saline is the treatment of choice for restoration of blood pressure. Captopril may be removed from the general circulation by hemodialysis.

DOSAGE AND ADMINISTRATION: CAPOTEN (captopril) should be taken one hour before meals. In hypertension, CAPOTEN may be dosed bid or tid. Dosage must be individualized; see DOSAGE AND ADMINISTRATION section of package insert for detailed information regarding dosage in hypertension and in heart failure. Because CAPOTEN (captopril) is excreted primarily by the kidneys, dosage adjustments are recommended for patients with impaired renal function.

Consult package insert before prescribing CAPOTEN (captopril).

HOW SUPPLIED: Available in tablets of 12.5, 25, 50, and 100 mg in bottles of 100 (25 mg and 50 mg also available in bottles of 1000), and in UNIMATIC® unit-dose packs of 100 tablets.

Intra-Aortic Balloon Pumping.

Because aggressive intervention saves lives.

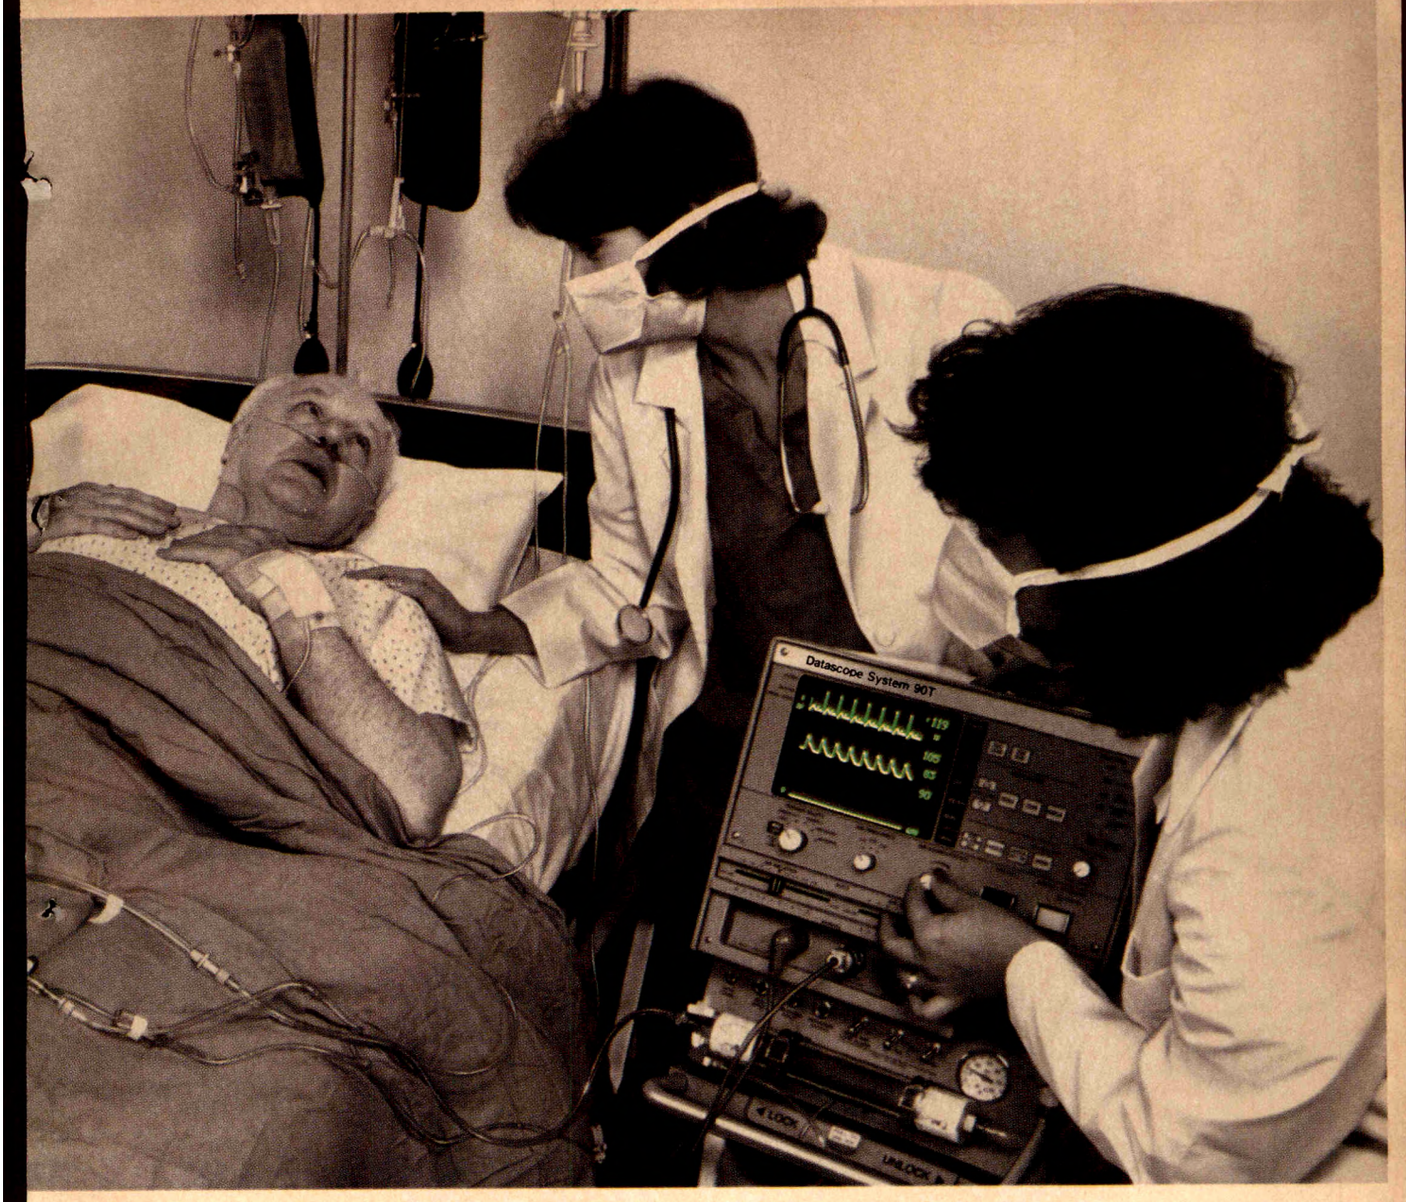
Today hospitals of every size are using IABP to give their patients the greatest possible chance for survival.

More than 70% of all admissions related to ischemic heart disease present at hospitals which do not perform open-heart surgery. In the face of this statistic, hospitals large and small are intervening more aggressively, reducing the mortality rates dramatically. *And intra-aortic balloon pumping is significant in the achievement of these results.*

Datascope has been the innovative force in developing IABP as a life-saving therapy in hospitals of every size. Today, in fact, almost half of all the hospitals we serve do not have open-heart facilities. However, they are aggressively using IABP therapy to support many of their unstable cardiac patients.

A commitment to product innovation.
Since Datascope first introduced IABP in 1969, our resources have been dedicated to its steady development.

The System 90 console and 90T transport balloon pumps



represent fifth generation technology. The simple, automatic operation of these systems has resulted in more Datascope units being put into service than all other pumps combined.

Steady improvements in safety and ease of catheter insertion (from our introduction of the first percutaneous balloon catheter to our newest prefolded 9.5 French dual lumen catheter) have resulted in more aggressive use of IABP therapy at the earliest indication.

Comprehensive educational support.

Datascope's Clinical Education Services Department offers a level of support second to none in IABP, and rare even within the field of cardiac care.

For the many hospitals new to IABP, we work closely with staff members until they are comfortable with every aspect of balloon pumping. We teach theory and practice, including how to use the System 90T to transport patients to hospitals with open-heart facilities.

Our clinical education specialists also work closely with hospitals already providing IABP, conducting seminars and helping them develop their own in-house educational programs.

A dedicated service network.

With our staff of over 50 technical service representatives dedicated exclusively to your Datascope products, you can depend on us for routine and emergency maintenance 24 hours a day, seven days a week. To make certain you are never without the use of your equipment, loaner units are available. And because there are occasional unplanned demands for IABP, we can help you meet unexpected requirements through our equipment rental program.

You are invited to draw from the many resources of Datascope in the implementation of a new IABP program or in support of your existing program.

For information and assistance, call (201) 265-8800. Or write: Datascope, P.O. Box 5, Paramus, NJ 07653-0005.

CORONARY ARTERY DISEASE

501 **Effects of Encainide, Flecainide, Imipramine and Moricizine on Ventricular Arrhythmias During the Year After Acute Myocardial Infarction: The CAPS**

The Cardiac Arrhythmia Pilot Study (CAPS) Investigators

The National Heart, Lung, and Blood Institute initiated the Cardiac Arrhythmia Pilot Study (CAPS) to determine the feasibility of suppressing ventricular arrhythmias after acute myocardial infarction. Ten centers enrolled 502 patients younger than 75 years of age with ≥10 ventricular premature complexes (VPC) per hour. Patients were randomized to 1 of 5 treatment tracks with 2 drugs that included encainide, flecainide, imipramine, moricizine and placebo. During a double-blind drug selection phase, drugs or dosage were changed to achieve ≥70% reduction in VPC frequency and >90% reduction in runs of VPC. Patients in the 5 treatment arms were similar in age, sex, clinical characteristics, VPC frequency, left ventricular ejection fraction and concomitant drug treatment. Encainide and flecainide met the CAPS efficacy goals and were well tolerated.

510 **Adoption of Thrombolytic Therapy in the Management of Acute Myocardial Infarction**

Mark A. Hlatky, Harry E. Cotugno, Christopher O'Connor, Daniel B. Mark, David B. Pryor, and Robert M. Califf

A national survey of 1,065 physicians was performed to document use of thrombolytic therapy. Thrombolytic therapy was used in early 1987 by 66% of respondents. Most used intravenous administration, typically 1.5 million units of streptokinase. Duration of symptoms was the key factor in the decision to use thrombolytic therapy; 45% of physicians set a time limit of <4 hours and 85% set a limit of <6 hours. Despite widespread acceptance, however, most physicians used thrombolytic therapy for <25% of their patients with acute myocardial infarction.

The benefit of antianginal protection plus safety...

CARDIZEM®: A FULLER LIFE

diltiazem HCl/Marion

- ***A remarkable safety profile***[1-6]
  The low incidence of side effects with Cardizem allows patients to feel better.
- ***Protection against angina attacks***[1,5,7-9]
  The predictable efficacy of Cardizem in stable exertional and vasospastic angina allows patients to do more.*
- ***A decrease in myocardial oxygen demand***
  Resulting from a lowered heart rate-blood pressure product.[5]
- ***Compatible with other antianginals***[6†]
- ***Safe in angina with coexisting hypertension, COPD, asthma, or PVD***[1,3,5,6]

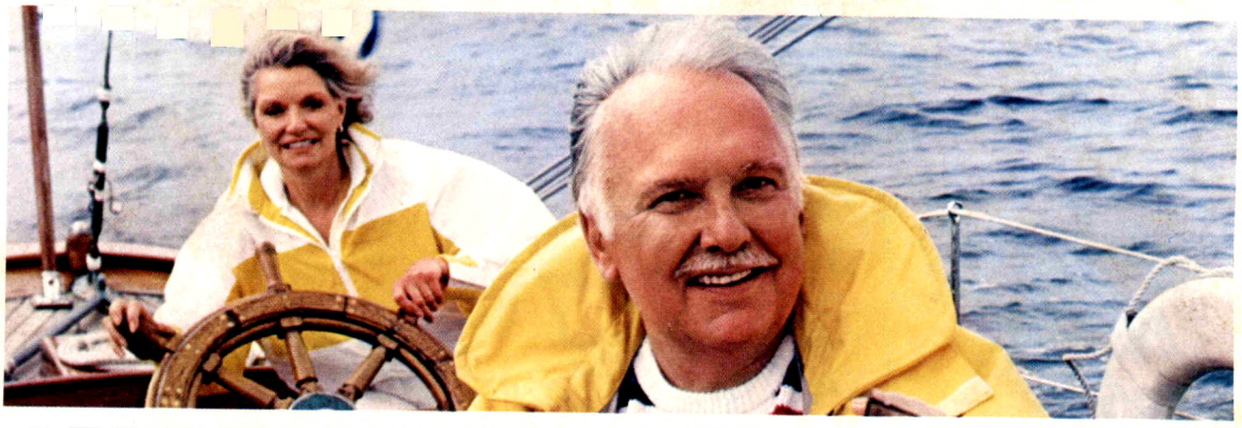
60 mg 90/120 mg GREATER DOSAGE FLEXIBILITY

**CARDIZEM® (diltiazem HCl) is indicated in the treatment of angina pectoris due to coronary artery spasm and in the management of chronic stable angina (classic effort-associated angina) in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents.*

†See Warnings and Precautions.

Please see brief summary of prescribing information on the next page.

0778A8



CARDIZEM® ANTIANGINAL PROTECTION PLUS SAFETY

diltiazem HCl/Marion

Usual maintenance dosage range: 180-360 mg/day

BRIEF SUMMARY
Professional Use Information

CARDIZEM®
(diltiazem HCl)
30 mg, 60 mg, 90 mg, and 120 mg Tablets

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block except in the presence of a functioning ventricular pacemaker, (3) patients with hypotension (less than 90 mm Hg systolic), and (4) patients who have demonstrated hypersensitivity to the drug.

WARNINGS

1. ***Cardiac Conduction.*** *CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (six of 1,243 patients for 0.48%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg of diltiazem.*
2. ***Congestive Heart Failure.*** *Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.*
3. ***Hypotension.*** *Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.*
4. ***Acute Hepatic Injury.*** *In rare instances, significant elevations in enzymes such as alkaline phosphatase, LDH, SGOT, SGPT, and other phenomena consistent with acute hepatic injury have been noted. These reactions have been reversible upon discontinuation of drug therapy. The relationship to CARDIZEM is uncertain in most cases, but probable in some. (See PRECAUTIONS.)*

PRECAUTIONS

General. *CARDIZEM (diltiazem hydrochloride) is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.*

Dermatological events (see ADVERSE REACTIONS section) may be transient and may disappear despite continued use of CARDIZEM. However, skin eruptions progressing to erythema multiforme and/or exfoliative dermatitis have also been infrequently reported. Should a dermatologic reaction persist, the drug should be discontinued.

Drug Interaction. *Due to the potential for additive effects, caution and careful titration are warranted in patients receiving CARDIZEM concomitantly with any agents known to affect cardiac contractility and/or conduction. (See WARNINGS.)*

Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS.)

As with all drugs, care should be exercised when treating patients with multiple medications. CARDIZEM undergoes biotransformation by cytochrome P-450 mixed function oxidase. Coadministration of CARDIZEM with other agents which follow the same route of biotransformation may result in the competitive inhibition of metabolism. Dosages of similarly metabolized drugs, particularly those of low therapeutic ratio or in patients with renal and/or hepatic impairment, may require adjustment when starting or stopping concomitantly administered CARDIZEM to maintain optimum therapeutic blood levels.

Beta-blockers: *Controlled and uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities.*

Administration of CARDIZEM (diltiazem hydrochloride) concomitantly with propranolol in five normal volunteers resulted in increased propranolol levels in all subjects and bioavailability of propranolol was increased approximately 50%. If combination therapy is initiated or withdrawn in conjunction with propranolol, an adjustment in the propranolol dose may be warranted. (See WARNINGS.)

Cimetidine: *A study in six healthy volunteers has shown a significant increase in peak diltiazem plasma levels (58%) and area-under-the-curve (53%) after a one-week course of cimetidine at 1,200 mg per day and diltiazem 60 mg per day. Ranitidine produced smaller, nonsignificant increases. The effect may be mediated by cimetidine's known inhibition of hepatic cytochrome P-450, the enzyme system probably responsible for the first-pass metabolism of diltiazem. Patients currently receiving diltiazem therapy should be carefully monitored for a change in pharmacological effect when initiating and discontinuing therapy with cimetidine. An adjustment in the diltiazem dose may be warranted.*

Digitalis: *Administration of CARDIZEM with digoxin in 24 healthy male subjects increased plasma digoxin concentrations approximately 20%. Another investigator found no increase in digoxin levels in 12 patients with coronary artery disease. Since there have been conflicting results regarding the effect of digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing CARDIZEM therapy to avoid possible over- or under-digitalization. (See WARNINGS.)*

Carcinogenesis, Mutagenesis, Impairment of Fertility. *A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.*

Pregnancy. *Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/ postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.*

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. *Diltiazem is excreted in human milk. One report suggests that concentrations in breast milk may approximate serum levels. If use of CARDIZEM is deemed essential, an alternative method of infant feeding should be instituted.*

Pediatric Use. *Safety and effectiveness in children have not been established.*

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

The following represent occurrences observed in clinical studies which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences as well as their frequency of presentation are: edema (2.4%), headache (2.1%), nausea (1.9%), dizziness (1.5%), rash (1.3%), asthenia (1.2%). In addition, the following events were reported infrequently (less than 1%):

Cardiovascular:	*Angina, arrhythmia, AV block (first degree), AV block (second or third degree—see conduction warning), bradycardia, congestive heart failure, flushing, hypotension, palpitations, syncope.*
Nervous System:	*Amnesia, depression, gait abnormality, hallucinations, insomnia, nervousness, paresthesia, personality change, somnolence, tinnitus, tremor.*
Gastrointestinal:	*Anorexia, constipation, diarrhea, dysgeusia, dyspepsia, mild elevations of alkaline phosphatase, SGOT, SGPT, and LDH (see hepatic warnings), vomiting, weight increase.*
Dermatologic:	*Petechiae, pruritus, photosensitivity, urticaria.*
Other:	*Amblyopia, CPK elevation, dyspnea, epistaxis, eye irritation, hyperglycemia, nasal congestion, nocturia, osteoarticular pain, polyuria, sexual difficulties.*

The following postmarketing events have been reported infrequently in patients receiving CARDIZEM: alopecia, gingival hyperplasia, erythema multiforme, and leukopenia. However, a definitive cause and effect between these events and CARDIZEM therapy is yet to be established. *Issued 6/87*

515 Trends in Physician Management of Uncomplicated Acute Myocardial Infarction, 1970 to 1987

Mark A. Hlatky, Harry E. Cotugno, Daniel B. Mark, Christopher O'Connor, Robert M. Califf, and David B. Pryor

To document trends in management of uncomplicated acute myocardial infarction, we surveyed 1,065 physicians. Responses were compared with previous surveys of 1970 and 1979. In 1987, patients were kept in the hospital half as long as in 1970, and permitted to resume activities sooner after discharge. Use of coronary angiography has increased, especially in younger patients and those with evidence of jeopardized myocardium. Aspirin and β blocker use has doubled to 80%. The survey documents an increasingly aggressive approach to the patient with uncomplicated acute myocardial infarction.

519 Influence of Long-Term Metoprolol Treatment on Early and Late Exercise Test Performance After Acute Myocardial Infarction

Gunnar Olsson, Nina Rehnqvist, Ulla Freyschuss, and Staffan Zetterquist

In a double-blind randomized study, 154 postinfarction patients treated with metoprolol 100 mg twice daily were compared with 147 patients treated with placebo for 3 years. The effect of study treatment on exercise performance during a 3-year follow-up was evaluated. In the metoprolol-treated group maximal heart rates were significantly reduced ($p < 0.001$) but maximal exercise capacity on a bicycle exercise test was similar. Exercise-induced angina and ST depression early after the infarction were reduced by metoprolol. A multiple logistic regression analysis showed that exercise performance at 6 weeks, male sex, previous infarction, therapy without β blocker and left ventricular heart failure carried independent prognostic information. Further, exercise-induced ST depression ≥ 1 mm in the placebo-treated patients was associated with worsened prognosis. Death, reinfarction or both were significantly reduced by metoprolol treatment in patients with exercise-induced ST depressions ≥ 1 mm at the 6-week test.

524 Improved Survival up to Four Years After Early Coronary Thrombolysis

Detlef G. Mathey, Joachim Schofer, Florence H. Sheehan, Hans-Joachim Krebber, Marlene Justen, Georg Rodewald, H.T. Dodge, and Walter Bleifeld

Prognosis up to 4 years after thrombolytic therapy for acute myocardial infarction was evaluated in 227 patients. Hospital and 4-year mortality rates were significantly reduced in patients with a patent infarct artery at the end of the acute catheterization. Early bypass surgery in the patent group appeared to improve left ventricular function, and further enhance survival by reducing the incidence of fatal reinfarction and cardiogenic shock.

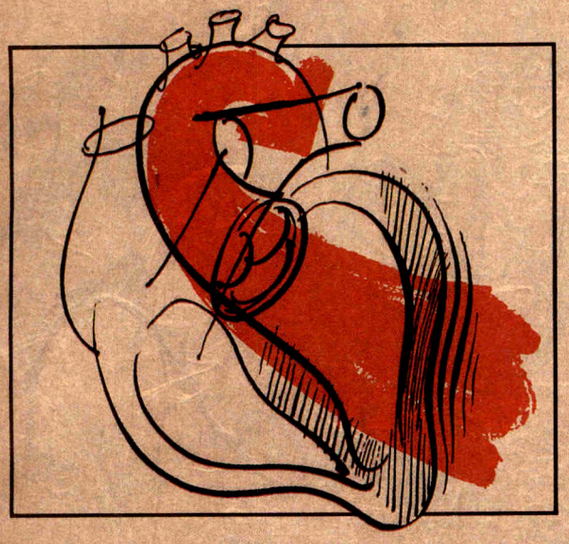
New findings in CHF.



INOTROPY DELIVERS:
Significant increase in ejection fraction compared to an angiotensin-converting enzyme (ACE) inhibitor and placebo.[1]

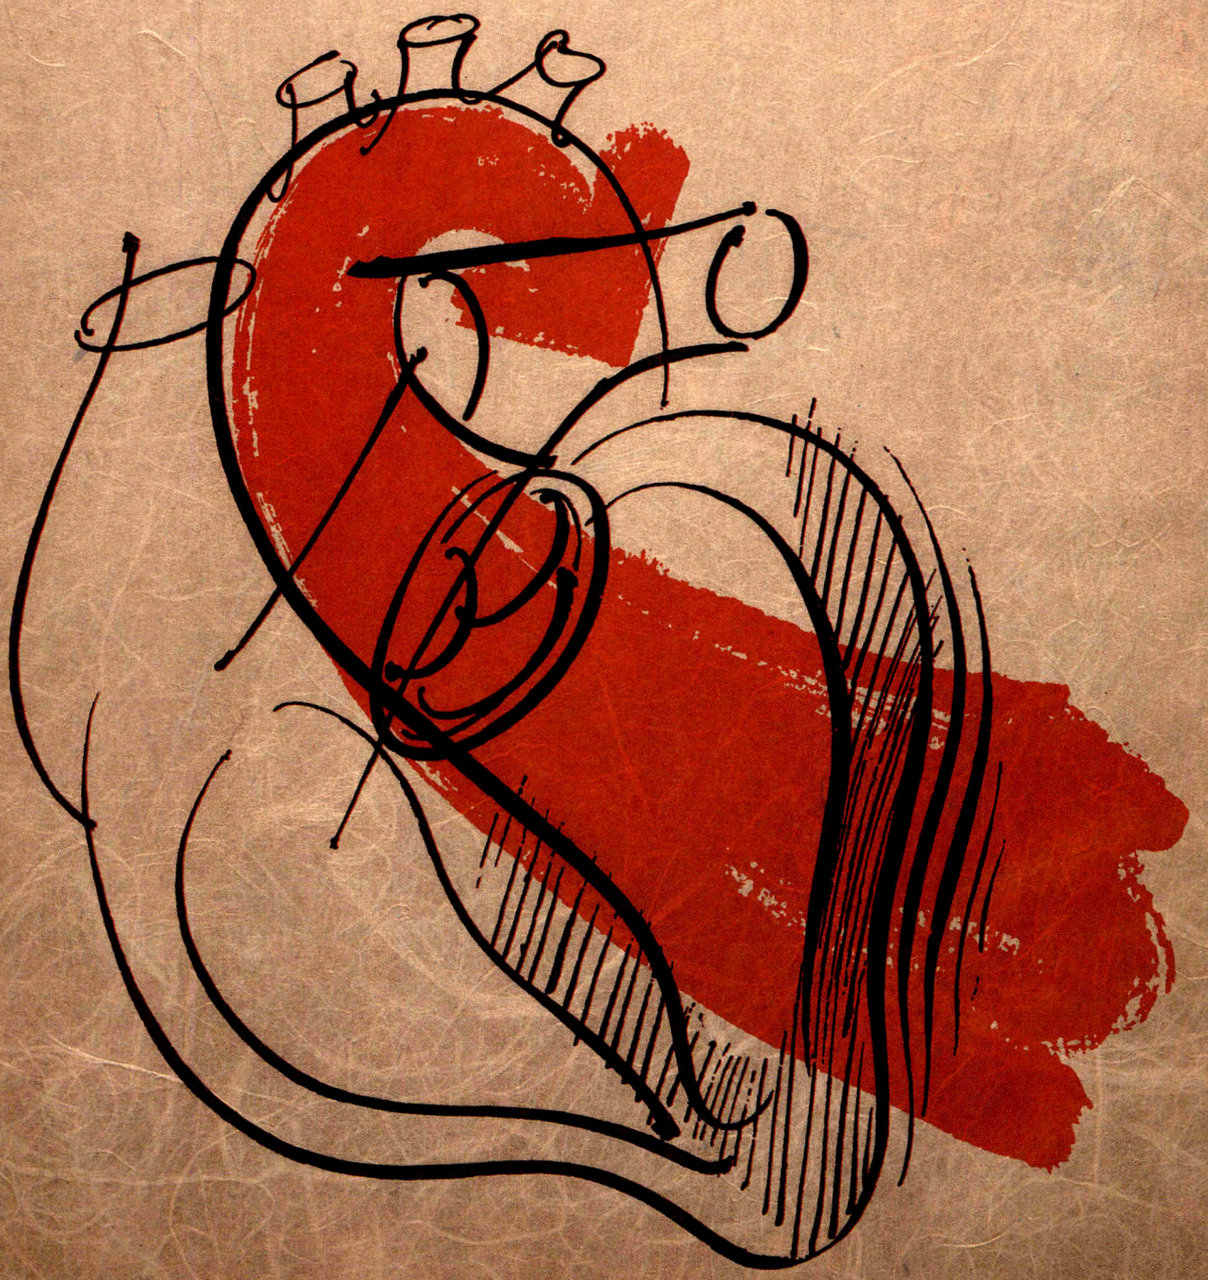
CLINICAL BENEFIT:
Improvement in exercise tolerance not significantly different from ACE inhibitor.[2]

OTHER NEW RESEARCH:
Integral part of all CHF treatment regimens that increased patient survival.[3,4]

See results of new studies on following pages.▶

NEW FINDINGS CONTINUE TO AFFIRM:

LANOXIN®... integral part of regimens that increase survival in CHF patients.[3,4]

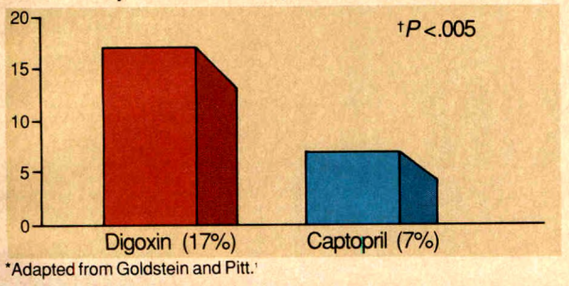


Wellcome

Improves ejection fraction–an important predictor of survival.

In a long-term double-blind study of 300 patients with mild to moderate congestive heart failure, digoxin produced a significant increase in ejection fraction compared to captopril and placebo.[1] Ejection fraction, a measure of ventricular performance, has proven to be an important predictor of survival.[3]

Percent Improvement in Ejection Fraction*†



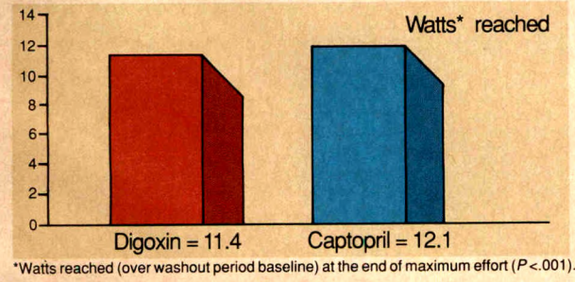
*Adapted from Goldstein and Pitt.[1]

Improves exercise tolerance and cardiac output.

A recent study showed digoxin significantly improved exercise tolerance and O_2 consumption over placebo.[2] Similar results were produced with captopril.[2]

In another study, there was no significant statistical difference between the digoxin and captopril groups in exercise tolerance and functional class.[1] In addition, digoxin has been shown to produce significant improvement in cardiac output in patients at rest as well as during exercise.[5]

Exercise Tolerance–Digoxin vs Captopril[2]



*Watts reached (over washout period baseline) at the end of maximum effort (P <.001).

No difference was observed between the two active treatments. A significant increase in exercise tolerance over respective washout periods was demonstrated.

P 24,168

An integral part of all regimens that increase survival.

In a double-blind trial, patients with chronic congestive heart failure (CHF) undergoing treatment with digoxin and diuretics received additional treatment with prazosin, hydralazine plus isosorbide dinitrate (ISDN), or placebo. The results showed that the combination of digoxin, diuretics, hydralazine, and ISDN was the most effective for maximizing survival in patients with CHF.[3] Similar beneficial effects on mortality were found in the CONSENSUS Trial Study Group when enalapril was combined with diuretics and digoxin.[4]

IN THE EARLY TREATMENT OF CHF

LANOXIN®
(digoxin) Tablets

Unique support for the failing heart.

See brief summary of prescribing information on the next page.

LANOXIN® (DIGOXIN) TABLETS

125 μg (0.125 mg) Scored I.D. Imprint Y3B (yellow)
250 μg (0.25 mg) Scored I.D. Imprint X3A (white)
500 μg (0.5 mg) Scored I.D. Imprint T9A (green)

Before using Lanoxin Tablets, the physician should be thoroughly familiar with the basic pharmacology of this drug as well as its drug interactions, indications, and usage.

DESCRIPTION: Lanoxin is digoxin, one of the cardiac (or digitalis) glycosides, a closely related group of drugs having in common specific effects on the myocardium.

INDICATIONS AND USAGE:

Heart Failure: The increased cardiac output resulting from the inotropic action of digoxin ameliorates the disturbances characteristic of heart failure (venous congestion, edema, dyspnea, orthopnea and cardiac asthma).

Digoxin is more effective in "low output" (pump) failure than in "high output" heart failure secondary to arteriovenous fistula, anemia, infection or hyperthyroidism.

Digoxin is usually continued after failure is controlled, unless some known precipitating factor is corrected. Studies have shown, however, that even though hemodynamic effects can be demonstrated in almost all patients, corresponding improvement in the signs and symptoms of heart failure is not necessarily apparent. Therefore, in patients in whom digoxin may be difficult to regulate, or in whom the risk of toxicity may be great (e.g., patients with unstable renal function or whose potassium levels tend to fluctuate) a cautious withdrawal of digoxin may be considered. If digoxin is discontinued, the patient should be regularly monitored for clinical evidence of recurrent heart failure.

CONTRAINDICATIONS: Digitalis glycosides are contraindicated in ventricular fibrillation.

In a given patient, an untoward effect requiring permanent discontinuation of other digitalis preparations usually constitutes a contraindication to digoxin. Hypersensitivity to digoxin itself is a contraindication to its use. Allergy to digoxin, though rare, does occur. It may not extend to all such preparations, and another digitalis glycoside may be tried with caution.

WARNINGS: Digitalis alone or with other drugs has been used in the treatment of obesity. This use of digoxin or other digitalis glycosides is unwarranted. Moreover, since they may cause potentially fatal arrhythmias or other adverse effects, the use of these drugs solely for the treatment of obesity is dangerous.

Anorexia, nausea, vomiting and arrhythmias may accompany heart failure or may be indications of digitalis intoxication. Clinical evaluation of the cause of these symptoms should be attempted before further digitalis administration. In such circumstances determination of the serum digoxin concentration may be an aid in deciding whether or not digitalis toxicity is likely to be present. If the possibility of digitalis intoxication cannot be excluded, cardiac glycosides should be temporarily withheld, if permitted by the clinical situation.

Patients with renal insufficiency require smaller than usual maintenance doses of digoxin (see DOSAGE AND ADMINISTRATION section in the complete prescribing information).

Heart failure accompanying acute glomerulonephritis requires extreme care in digitalization. Relatively low loading and maintenance doses and concomitant use of antihypertensive drugs may be necessary and careful monitoring is essential. Digoxin should be discontinued as soon as possible.

Patients with severe carditis, such as carditis associated with rheumatic fever or viral myocarditis, are especially sensitive to digoxin-induced disturbances of rhythm.

Newborn infants display considerable variability in their tolerance to digoxin. Premature and immature infants are particularly sensitive, and dosage must not only be reduced but must be individualized according to their degree of maturity.

Note: Digitalis glycosides are an important cause of accidental poisoning in children.

PRECAUTIONS:

General: Digoxin toxicity develops more frequently and lasts longer in patients with renal impairment because of the decreased excretion of digoxin. Therefore, it should be anticipated that dosage requirements will be decreased in patients with moderate to severe renal disease (see DOSAGE AND ADMINISTRATION section in the complete prescribing information).

Because of the prolonged half-life, a longer period of time is required to achieve an initial or new steady-state concentration in patients with renal impairment than in patients with normal renal function.

In patients with hypokalemia, toxicity may occur despite serum digoxin concentrations within the "normal range", because potassium depletion sensitizes the myocardium to digoxin. Therefore, it is desirable to maintain normal serum potassium levels in patients being treated with digoxin.

Hypokalemia may result from diuretic, amphotericin B or corticosteroid therapy, and from dialysis or mechanical suction of gastrointestinal secretions. It may also accompany malnutrition, diarrhea, prolonged vomiting, old age and long-standing heart failure. In general, rapid changes in serum potassium or other electrolytes should be avoided, and intravenous treatment with potassium should be reserved for special circumstances as described below (see TREATMENT OF ARRHYTHMIAS PRODUCED BY OVERDOSAGE section).

Calcium, particularly when administered rapidly by the intravenous route, may produce serious arrhythmias in digitalized patients. Hypercalcemia from any cause predisposes the patient to digitalis toxicity. On the other hand, hypocalcemia can nullify the effects of digoxin in man; thus, digoxin may be ineffective until serum calcium is restored to normal. These interactions are related to the fact that calcium affects contractility and excitability of the heart in a manner similar to digoxin.

Hypomagnesemia may predispose to digitalis toxicity. If low magnesium levels are detected in a patient on digoxin, replacement therapy should be instituted.

Quinidine, verapamil, and amiodarone cause a rise in serum digoxin concentration, with the implication that digitalis intoxication may result. This rise appears to be proportional to the dose. The effect is mediated by a reduction in the digoxin clearance and, in the case of quinidine, decreased volume of distribution as well.

Certain antibiotics may increase digoxin absorption in patients who convert digoxin to inactive metabolites in the gut (see Pharmacokinetics portion of the CLINICAL PHARMACOLOGY section in the complete prescribing information). Recent studies have shown that specific colonic bacteria in the lower gastrointestinal tract convert digoxin to cardioinactive reduction products, thereby reducing its bioavailability. Although inactivation of these bacteria by antibiotics is rapid, the serum digoxin concentration will rise at a rate consistent with the elimination half-life of digoxin. The magnitude of rise in serum digoxin concentration relates to the extent of bacterial inactivation, and may be as much as two-fold in some cases.

Patients with acute myocardial infarction or severe pulmonary disease may be unusually sensitive to digoxin-induced disturbances of rhythm.

Atrial arrhythmias associated with hypermetabolic states (e.g. hyperthyroidism) are particularly resistant to digoxin treatment. Large doses of digoxin are not recommended as the only treatment of these arrhythmias and care must be taken to avoid toxicity if large doses of digoxin are required. In hypothyroidism, the digoxin requirements are reduced. Digoxin responses in patients with compensated thyroid disease are normal.

Reduction of digoxin dosage may be desirable prior to electrical cardioversion to avoid induction of ventricular arrhythmias, but the physician must consider the consequences of rapid increase in ventricular response to atrial fibrillation if digoxin is withheld 1 to 2 days prior to cardioversion. If there is a suspicion that digitalis toxicity exists, elective cardioversion should be delayed. If it is not prudent to delay cardioversion, the energy level selected should be minimal at first and carefully increased in an attempt to avoid precipitating ventricular arrhythmias.

Incomplete AV block, especially in patients with Stokes-Adams attacks, may progress to advanced or complete heart block if digoxin is given.

In some patients with sinus node disease (i.e. Sick Sinus Syndrome), digoxin may worsen sinus bradycardia or sino-atrial block.

In patients with Wolff-Parkinson-White Syndrome and atrial fibrillation, digoxin can enhance transmission of impulses through the accessory pathway. This effect may result in extremely rapid ventricular rates and even ventricular fibrillation.

Digoxin may worsen the outflow obstruction in patients with idiopathic hypertrophic subaortic stenosis (IHSS). Unless cardiac failure is severe, it is doubtful whether digoxin should be employed.

Patients with chronic constrictive pericarditis may fail to respond to digoxin. In addition, slowing of the heart rate by digoxin in some patients may further decrease cardiac output.

Patients with heart failure from amyloid heart disease or constrictive cardiomyopathies respond poorly to treatment with digoxin.

Digoxin is not indicated for the treatment of sinus tachycardia unless it is associated with heart failure.

Digoxin may produce false positive ST-T changes in the electrocardiogram during exercise testing.

Intramuscular injection of digoxin is extremely painful and offers no advantages unless other routes of administration are contraindicated.

Laboratory Tests: Patients receiving digoxin should have their serum electrolytes and renal function (BUN and/or serum creatinine) assessed periodically; the frequency of assessments will depend on the clinical setting. For discussion of serum digoxin concentrations, see DOSAGE AND ADMINISTRATION section in the complete prescribing information.

Drug Interactions: Potassium-depleting *corticosteroids* and *diuretics* may be major contributing factors to digitalis toxicity. *Calcium*, particularly if administered rapidly by the intravenous route, may produce serious arrhythmias in digitalized patients. *Quinidine*, *verapamil*, and *amiodarone* cause a rise in serum digoxin concentration, with the implication that digitalis intoxication may result. Certain *antibiotics* increase digoxin absorption in patients who inactivate digoxin by bacterial metabolism in the lower intestine, so that digitalis intoxication may result. *Propantheline* and *diphenoxylate*, by decreasing gut motility, may increase digoxin absorption. *Antacids*, *kaolin-pectin*, *sulfasalazine*, *neomycin*, *cholestyramine* and certain *anticancer drugs* may interfere with intestinal digoxin absorption, resulting in unexpectedly low serum concentrations. There have been inconsistent reports regarding the effects of other drugs on the serum digoxin concentration. *Thyroid* administration to a digitalized hypothyroid patient may increase the dose requirement of digoxin. Concomitant use of digoxin and *sympathomimetics* increases the risk of cardiac arrhythmias because both enhance ectopic pacemaker activity. *Succinylcholine* may cause a sudden extrusion of potassium from muscle cells, and may thereby cause arrhythmias in digitalized patients. Although ß adrenergic blockers or calcium channel blockers and digoxin may be useful in combination to control atrial fibrillation, their additive effects on AV node conduction can result in complete heart block.

Due to the considerable variability of these interactions, digoxin dosage should be carefully individualized when patients receive coadministered medications.

Carcinogenesis, Mutagenesis, Impairment of Fertility: There have been no long-term studies performed in animals to evaluate carcinogenic potential.

Pregnancy: ***Teratogenic Effects:*** Pregnancy Category C. Animal reproduction studies have not been conducted with digoxin. It is also not known whether digoxin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Digoxin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: Studies have shown that digoxin concentrations in the mother's serum and milk are similar. However, the estimated daily dose to a nursing infant will be far below the usual infant maintenance dose. Therefore, this amount should have no pharmacologic effect upon the infant. Nevertheless, caution should be exercised when digoxin is administered to a nursing woman.

ADVERSE REACTIONS: The frequency and severity of adverse reactions to digoxin depend on the dose and route of administration, as well as on the patient's underlying disease or concomitant therapies (see PRECAUTIONS section). The overall incidence of adverse reactions has been reported as 5 to 20%, with 15 to 20% of them being considered serious (one to four percent of patients receiving digoxin). Evidence suggests that the incidence of toxicity has decreased since the introduction of the serum digoxin assay and improved standardization of digoxin tablets. Cardiac toxicity accounts for about one-half, gastrointestinal disturbances for about one-fourth, and CNS and other toxicity for about one-fourth of these adverse reactions.

Adults:

Cardiac—Unifocal or multiform ventricular premature contractions, especially in bigeminal or trigeminal patterns, are the most common arrhythmias associated with digoxin toxicity in adults with heart disease.

Ventricular tachycardia may result from digitalis toxicity. Atrioventricular (AV) dissociation, accelerated junctional (nodal) rhythm and atrial tachycardia with block are also common arrhythmias caused by digoxin overdosage.

Excessive slowing of the pulse is a clinical sign of digoxin overdosage. AV block (Wenckebach) of increasing degree may proceed to complete heart block.

Note: The electrocardiogram is fundamental in determining the presence and nature of these cardiac disturbances. Digoxin may also induce other changes in the ECG (e.g. PR prolongation, ST depression), which represent digoxin effect and may or may not be associated with digitalis toxicity.

Gastrointestinal—Anorexia, nausea, vomiting and less commonly diarrhea are common early symptoms of overdosage. However, uncontrolled heart failure may also produce such symptoms. Digitalis toxicity very rarely may cause abdominal pain and hemorrhagic necrosis of the intestines.

CNS—Visual disturbances (blurred or yellow vision), headache, weakness, apathy and psychosis can occur.

Other—Gynecomastia is occasionally observed.

Infants and Children: Toxicity differs from the adult in a number of respects. Anorexia, nausea, vomiting, diarrhea and CNS disturbances may be present but are rare as initial symptoms in infants. Cardiac arrhythmias are more reliable signs of toxicity. Digoxin in children may produce any arrhythmia. The most commonly encountered are conduction disturbances or supraventricular tachyarrhythmias, such as atrial tachycardia with or without block, and junctional (nodal) tachycardia. Ventricular arrhythmias are less common. Sinus bradycardia may also be a sign of impending digoxin intoxication, especially in infants, even in the absence of first degree heart block. Any arrhythmia or alteration in cardiac conduction that develops in a child taking digoxin should initially be assumed to be a consequence of digoxin intoxication.

TREATMENT OF ARRHYTHMIAS PRODUCED BY OVERDOSAGE:

Adults: Digoxin should be discontinued until all signs of toxicity are gone. Discontinuation may be all that is necessary if toxic manifestations are not severe and appear only near the expected time for maximum effect of the drug.

Potassium salts are commonly used, particularly if hypokalemia is present. Potassium chloride in divided oral doses totaling 3 to 6 grams of the salt (40 to 80 mEq K+) for adults may be given provided renal function is adequate (see below for potassium recommendations in Infants and Children).

When correction of the arrhythmia is urgent and the serum potassium concentration is low or normal, potassium should be administered intravenously in 5% dextrose injection. For adults, a total of 40 to 80 mEq (diluted to a concentration of 40 mEq per 500 ml) may be given at a rate not exceeding 20 mEq per hour, or slower if limited by pain due to local irritation. Additional amounts may be given if the arrhythmia is uncontrolled and potassium well-tolerated. ECG monitoring should be performed to watch for any evidence of potassium toxicity (e.g. peaking of T waves) and to observe the effect on the arrhythmia. The infusion may be stopped when the desired effect is achieved.

Note: Potassium should not be used and may be dangerous in heart block due to digoxin, unless primarily related to supraventricular tachycardia.

Other agents that have been used for the treatment of digoxin intoxication include lidocaine, procainamide, propranolol and phenytoin, although use of the latter must be considered experimental. In advanced heart block, temporary ventricular pacing may be beneficial. Digoxin Immune Fab (Ovine), Digibind®, can be used to reverse potentially life-threatening digoxin (or digitoxin) intoxication. Improvement in signs and symptoms of digitalis toxicity usually begins within ½ hour of Digibind administration. Each 40 mg vial of Digibind will neutralize 0.6 mg of digoxin (which is a usual body store of an adequately digitalized 70 kg patient).

Infants and Children: See Adult section for general recommendations for the treatment of arrhythmias produced by overdosage and for cautions regarding the use of potassium.

If a potassium preparation is used to treat toxicity, it may be given orally in divided doses totaling 1 to 1.5 mEq K+ per kilogram (kg) body weight (1 gram of potassium chloride contains 13.4 mEq K+).

When correction of the arrhythmia with potassium is urgent, approximately 0.5 mEq/kg of potassium per hour may be given intravenously, with careful ECG monitoring. The intravenous solution of potassium should be dilute enough to avoid local irritation; however, especially in infants, care must be taken to avoid intravenous fluid overload.

DOSAGE AND ADMINISTRATION: Recommended dosages are average values that may require considerable modification because of individual sensitivity or associated conditions. Diminished renal function is the most important factor requiring modification of recommended doses.

In deciding the dose of digoxin, several factors must be considered:

1. The disease being treated. Atrial arrhythmias may require larger doses than heart failure.
2. The body weight of the patient. Doses should be calculated based upon lean or ideal body weight.
3. The patient's renal function, preferably evaluated on the basis of creatinine clearance.
4. Age is an important factor in infants and children.
5. Concomitant disease states, drugs or other factors likely to alter the expected clinical response to digoxin (see PRECAUTIONS and Drug Interactions sections).

Consult complete product information before prescribing.

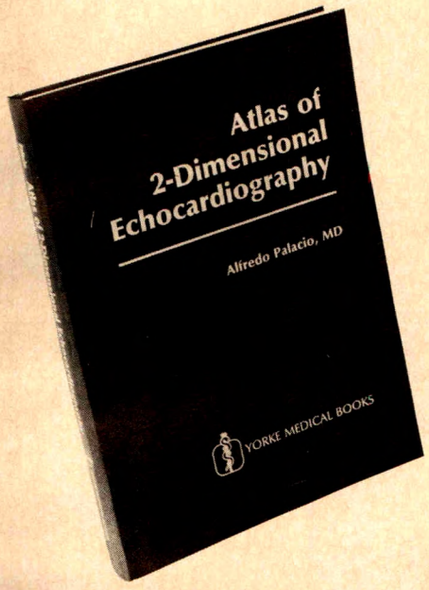
The First Practical Atlas of 2-D Echocardiography Ever Published



A "how-to-do-it" text/atlas presenting the broadest range of normal and abnormal 2-dimensional echocardiograms

Atlas of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Director of National Institute of Cardiology, Guayaquil, Ecuador
Foreword by David H. Spodick, MD, DSc
Professor of Medicine, University of Massachusetts Medical School; Director, Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts

ISBN 0-914316-35-4, 198 pp, illus., large format 8¼ × 12, March '83, $69.00

2-dimensional echocardiography complemented by M-mode echocardiography has become one of the most common noninvasive diagnostic tools used by the cardiologist. With publication of the ATLAS OF 2-DIMENSIONAL ECHOCARDIOGRAPHY, neophyte and expert alike now have available to them the most truly usable didactic presentation of the subject ever published.

A true atlas, this book provides in a **large 8¼ × 12 format 251 black and white half tones, 152 line drawings and 6 charts** which illustrate in exacting detail how to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads the reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations in its technical sections will ensure the superior level of performance of echocardiographic techniques that is a sine qua non for good results.

530 Factors of Importance for Prognosis in Men with Angina Pectoris Derived from a Random Population Sample. The Multifactor Primary Prevention Trial, Gothenburg, Sweden

Marianne Hagman, Lars Wilhelmsen, Kjell Pennert, and Hans Wedel

A random population sample of middle-aged men (n = 6,038) was followed for 11.3 years from a first screening. Men with uncomplicated angina pectoris (AP) had an incidence of fatal and nonfatal coronary artery disease (CAD) events 3 times higher than that of men without AP or myocardial infarction. Men with myocardial infarction with or without AP had an incidence of CAD events 7 to 8 times higher than that of men without AP or myocardial infarction. Similar differences were found for new cases of uncomplicated AP and myocardial infarction detected at a second screening carried out 4 years later and followed for 7.3 years. Elevated serum cholesterol, elevated blood pressure, smoking and angina attack score were independently associated with CAD endpoints during follow-up, with the increase in risk proving to be similar to the general population.

536 Assessment of Mitral Flow Velocity with Exercise by an Index of Stress-Induced Left Ventricular Ischemia in Coronary Artery Disease

George D. Mitchell, Richard C. Brunken, Markus Schwaiger, Bryan C. Donohue, Janine Krivokapich, and John S. Child

Exercise-induced myocardial ischemia results in both diastolic and systolic left ventricular (LV) dysfunction. To investigate the utility of Doppler assessment of LV diastolic function with exercise, 28 consecutive patients underwent digital stress echocardiography, measurement of mitral flow velocity by pulsed-wave Doppler and simultaneous stress thallium imaging. The percent increase in mean mitral flow velocity among controls was 101 ± 59 (n = 10), compared with 33 ± 24% in patients with stress-induced ischemia as evidenced by either exercise-induced wall-motion abnormalities by 2-dimensional echocardiography or perfusion defects by stress thallium imaging ($p < 0.005$). An increase in mean mitral flow velocity with exercise of >50% correctly identified 9 of 10 nonischemic control patients. An increase in mean mitral flow velocity of <50% predicted ischemia in 15 of 18 patients with evidence of stress-induced ischemia ($p < 0.005$). Thus, Doppler assessment of LV diastolic function with exercise expressed as the change in mean velocity of mitral flow is a useful indicator of stress-induced ischemia.

Continued on page A30

TONOCARD®
(TOCAINIDE HCl|MSD)

INDICATIONS AND USAGE

TONOCARD is indicated for the treatment of life-threatening ventricular arrhythmias.

TONOCARD is also indicated for the treatment of some patients with symptomatic ventricular arrhythmias.

Because TONOCARD has the potential to produce serious hematologic disorders (0.18 percent in clinical trials) particularly leukopenia or agranulocytosis (sometimes fatal), the use of TONOCARD should be reserved for patients in whom, in the opinion of the physician, the benefits of treatment outweigh the risks. (See WARNINGS.) For less serious arrhythmias alternative therapy with less severe toxicity, such as certain beta-blocking agents, should be considered.

Like all other antiarrhythmics, tocainide has not been shown to prevent sudden death in patients with serious ventricular ectopic activity, and also, like all other antiarrhythmics, it has potentially serious adverse effects, including the ability to worsen arrhythmias. It is therefore essential that each patient given tocainide be evaluated electrocardiographically and clinically prior to, and during, tocainide therapy to determine whether the response to tocainide supports continued treatment.

CONTRAINDICATIONS

Patients who are hypersensitive to this product or to local anesthetics of the amide type.

Patients with second- or third-degree atrioventricular block in the absence of an artificial ventricular pacemaker.

WARNINGS

Blood Dyscrasias: Agranulocytosis, bone marrow depression, leukopenia, neutropenia, hypoplastic anemia, thrombocytopenia and sequelae such as septicemia and septic shock have been reported in patients receiving TONOCARD. Most of these patients received TONOCARD within the recommended dosage range. Fatalities have occurred (with approximately 25 percent mortality in reported agranulocytosis cases). Since most of these events have been noted during the first 12 weeks of therapy, it is recommended that complete blood counts, including white cell, differential and platelet counts be performed, optimally, at weekly intervals for the first three months of therapy, and periodically thereafter. Complete blood counts should be performed promptly if the patient develops any signs of infection (such as fever, chills, sore throat, or stomatitis), bruising, or bleeding. If any of these hematologic disorders is identified, TONOCARD should be discontinued and appropriate treatment should be instituted if necessary. Blood counts usually return to normal within one month of discontinuation. Caution should be used in patients with pre-existing marrow failure or cytopenia of any type. (See ADVERSE REACTIONS.)

Acceleration of Ventricular Rate: Acceleration of ventricular rate occurs infrequently when antiarrhythmics are administered to patients with atrial flutter or fibrillation (see ADVERSE REACTIONS).

PRECAUTIONS

General

Pulmonary Fibrosis: Pulmonary fibrosis, interstitial pneumonitis, fibrosing alveolitis, pulmonary edema, and pneumonia, possibly drug related, have been reported in patients receiving TONOCARD. Many of these events occurred in patients who were seriously ill. The experiences are usually characterized by bilateral infiltrates on x-ray and are frequently associated with dyspnea and cough. Fever may or may not be present. Patients should be instructed to promptly report the development of any pulmonary symptoms such as exertional dyspnea, cough, or wheezing. Chest x-rays are advisable at that time. If these pulmonary disorders develop, TONOCARD should be discontinued. (See ADVERSE REACTIONS.)

In patients with known heart failure or minimal cardiac reserve, TONOCARD should be used with caution because of the potential for aggravating the degree of heart failure.

Caution should be used in the institution or continuation of antiarrhythmic therapy in the presence of signs of increasing depression of cardiac conductivity.

In patients with severe liver or kidney disease, the rate of drug elimination may be significantly decreased (see DOSAGE AND ADMINISTRATION).

Since antiarrhythmic drugs may be ineffective in patients with hypokalemia, the possibility of a potassium deficit should be explored and, if present, the deficit should be corrected.

Like all other oral antiarrhythmics, TONOCARD has been reported to increase arrhythmias in some patients (see ADVERSE REACTIONS).

Information for Patients

Patients should be instructed to promptly report the development of bruising or bleeding; any signs of infections such as fever, chills, sore throat, or soreness and ulcers in the mouth; any pulmonary symptoms, such as exertional dyspnea, cough, or wheezing; rash.

Laboratory Tests

As with other antiarrhythmics, abnormal liver function tests, particularly in the early stages of therapy, have been reported. Periodic monitoring of liver function should be considered. Hepatitis and jaundice have been reported in some patients.

Drug Interactions

Tocainide and lidocaine are pharmacodynamically similar. The concomitant use of these two agents may cause an increased incidence of adverse reactions, including central nervous system adverse reactions such as seizure.

Specific interaction studies with cimetidine, digoxin, metoprolol, and warfarin have been conducted; no clinically significant interaction was seen with cimetidine, digoxin, or warfarin; but tocainide and metoprolol had additive effects on wedge pressure and cardiac index. TONOCARD has also been used in open studies with digitalis, beta-blocking agents, other antiarrhythmic agents, anticoagulants, and diuretics without evidence of clinically significant interactions. Nevertheless, caution should be exercised in the use of multiple drug therapy.

Pregnancy

Pregnancy Category C. In a teratogenicity study in rabbits, tocainide was administered orally at doses of 25, 50, and 100 mg/kg/day (about 1 to 4 times the usual human dose). No evidence of a drug-related teratogenic effect was noted; however, these doses were maternotoxic and produced a dose-related increase in abortions and stillbirths. In a teratogenicity study in rats, an oral dose of 300 mg/kg/day (about 12 times the usual human dose) showed no evidence of treatment-related fetal malformations, but maternotoxicity and an increase in fetal resorptions were noted. An oral dose of 30 mg/kg/day (about twice the usual human dose) did not produce any adverse effects.

In reproduction studies in rats at maternotoxic oral doses of 200 and 300 mg/kg/day (about 8 and 12 times the usual human dose, respectively), dystocia, and delayed parturition occurred which was accompanied by an increase in stillbirths and decreased survival in offspring during the first week postpartum. Growth and viability of surviving offspring were not affected for the remainder of the lactation period.

There are no adequate and well-controlled studies in pregnant women. TONOCARD should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers

It is not known whether tocainide is secreted in human milk. Because many drugs are secreted in human milk and because of the potential for serious adverse reactions in nursing infants from TONOCARD, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use

Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

TONOCARD commonly produces minor, transient nervous system and gastrointestinal adverse reactions, but is otherwise generally well tolerated. TONOCARD has been evaluated in both short-term (n = 1,358) and long-term (n = 262) controlled studies as well as a compassionate use program. Dosages were lower in most of the controlled studies (1200 mg/day) and higher in the compassionate use program (1800 mg and more). In long-term (2-6 months) controlled studies, the most frequent adverse reactions were dizziness/vertigo (15.3 percent), nausea (14.5 percent), paresthesia (9.2 percent), and tremor (8.4 percent). These reactions were generally mild, transient, dose-related and reversible with a reduction in dosage, by

TONOCARD® (Tocainide HCl|MSD)

taking the drug with food, or by therapy discontinuation. Tremor, when present, may be useful as a clinical indicator that the maximum dose is being approached. Adverse reactions leading to therapy discontinuation occurred in 21 percent of patients in long-term controlled trials and were usually related to the nervous system or digestive system.

Adverse reactions occurring in greater than one percent of patients from the short-term and long-term controlled studies appear in the following table:

	Percent of Patients Controlled Studies	
	Short-term (n = 1,358)	Long-term (n = 262)
BODY AS A WHOLE		
Tiredness/drowsiness/ fatigue/lethargy/ lassitude/ sleepiness	1.6	0.8
Hot/cold feelings	0.5	1.5
CARDIOVASCULAR		
Hypotension	3.4	2.7
Bradycardia	1.8	0.4
Palpitations	1.8	0.4
Chest pain	1.6	0.4
Conduction disorders	1.5	0.0
Left ventricular failure	1.4	0.0
DIGESTIVE		
Nausea	15.2	14.5
Vomiting	8.3	4.6

Confusion/ disorientation/ hallucinations	2.1	2.7
Headache	2.1	4.6
Nervousness	1.5	0.4
Altered mood/ awareness	1.5	3.4
Incoordination/ unsteadiness/ walking disturbances	1.2	0.0
Anxiety	1.1	1.5
Ataxia	0.2	3.0
SKIN		
Diaphoresis	5.1	2.3
Rash/skin lesion	0.4	8.4
SPECIAL SENSES		
Blurred vision/visual disturbances	1.3	1.5
Tinnitus/ hearing loss	0.4	1.5
Nystagmus	0.0	1.1

An additional group of about 2,000 patients has been treated in a program allowing for the use of TONOCARD under compassionate use circumstances. These patients were seriously ill with the large majority on multiple drug therapy, and comparatively high doses of TONOCARD were used. Fifty-four percent of the patients continued in the program for one year or longer, and 12 percent were treated for longer than three years, with the longest duration of therapy being nine years. Adverse reactions leading to therapy discontinuation occurred in 12 percent of patients (usually central nervous system effects or rash). A tabulation of adverse reactions occurring in one percent or more of patients follows:

	Percent of Patients Compassionate Use (n = 1,927)
CARDIOVASCULAR	
Increased ventricular arrhythmias/PVCs	10.9
CHF/progression of CHF	4.0
Tachycardia	3.2
Hypotension	1.8
Conduction disorders	1.3
Bradycardia	1.0

SPECIAL SENSES	
Blurred vision/vision disturbances	10.0
Nystagmus	1.1

Adverse reactions occurring in less than one percent of patients in either the controlled studies or the compassionate use program or since the drug was marketed are as follows:

Body as a Whole: Septicemia; septic shock; syncope; vaso-vagal episodes; edema; fever; chills; cinchonism; asthenia; malaise.

Cardiovascular: Ventricular fibrillation; extension of acute myocardial infarction; cardiogenic shock; pulmonary embolism; angina; AV block; hypertension; claudication; increased QRS duration; pleurisy/pericarditis; prolonged QT interval; right bundle branch block; cardiomegaly; sinus arrest; vasculitis; orthostatic hypotension; cold extremities.

Digestive: Hepatitis, jaundice (see PRECAUTIONS), abnormal liver function tests; pancreatitis; abdominal pain/discomfort; constipation; dysphagia; gastrointestinal symptoms (including dyspepsia); stomatitis; dry mouth; thirst.

Hematologic: Agranulocytosis; bone marrow depression; hypoplastic anemia; hemolytic anemia; anemia; leukopenia; neutropenia; thrombocytopenia; eosinophilia.

Metabolic and Immune: Hypersensitivity Reaction (including some of the following symptoms or signs: rash, fever, joint pains, abnormal liver function tests, eosinophilia); increased ANA.

Musculoskeletal: Muscle cramps; muscle twitching/spasm; neck pain; pain radiating from neck; pressure on shoulder.

Nervous System/Psychiatric: Coma; convulsions/seizures; myasthenia gravis; depression; psychosis; psychic disturbances; agitation; decreased mental acuity; dysarthria; impaired memory; increased stuttering/slurred speech; insomnia/sleeping disturbances; local anesthesia; dream abnormalities.

Respiratory: Respiratory arrest; pulmonary edema; pulmonary fibrosis; fibrosing alveolitis; pneumonia; interstitial pneumonitis; dyspnea; hiccough; yawning.

Skin: Stevens-Johnson syndrome; exfoliative dermatitis; erythema multiforme; urticaria; alopecia; pruritus; pallor/flushed face.

Special Senses: Diplopia; earache; taste perversion/smell perversion.

Urogenital: Urinary retention; polyuria/increased diuresis.

Agranulocytosis, bone marrow depression, leukopenia, neutropenia, hypoplastic anemia, and thrombocytopenia have been reported (0.18 percent) in patients receiving TONOCARD in controlled trials and the compassionate use program. Most of these events have been noted during the first 12 weeks of therapy. (See WARNINGS.)

Pulmonary fibrosis, interstitial pneumonitis, fibrosing alveolitis, pulmonary edema, and pneumonia, possibly drug related, have been reported in patients receiving TONOCARD. The incidence of pulmonary fibrosis (including interstitial pneumonitis and fibrosing alveolitis) was 0.11 percent in controlled trials and the compassionate use program. These events usually occurred in seriously ill patients. Symptoms of these pulmonary disorders and/or x-ray changes usually occurred following 3-18 weeks of therapy and two patients died. (See PRECAUTIONS.)

A number of disorders, in which a causal relationship with TONOCARD has not been established, have been reported in seriously ill patients. These include: renal failure, renal dysfunction, myocardial infarction, cerebrovascular accidents, and transient ischemic attacks. These disorders may be related to the patient's underlying condition.

HOW SUPPLIED

Scored tablets containing 400 mg or 600 mg in bottles of 100 and unit-dose packages of 100.

541 Dynamics of Early and Late Left Ventricular Filling Determined by Doppler Two-Dimensional Echocardiography During Percutaneous Transluminal Coronary Angioplasty

Leigh K. Bowman, Michael W. Cleman, Henry S. Cabin, Barry L. Zaret, and C. Carl Jaffe

Doppler 2-dimensional echocardiography was used to measure ventricular filling during percutaneous transluminal coronary angioplasty (PTCA). During left anterior descending artery PTCA there was a 35% decrease in early peak filling rate from 269 ± 88 to 169 ± 55 ml/s ($p < 0.0005$). In circumflex or dominant right coronary artery PTCA the early peak filling rate decreased 15% from 325 ± 126 to 248 ± 137 ml/s ($p < 0.005$). Rather than an expected increase in atrial stroke volume and a decrease in early to late filling ratio during coronary occlusion, there was a 28% decrease in atrial stroke volume during left anterior descending coronary artery PTCA and a 6% decrease during right coronary and circumflex PTCA. Because of the decrease in both early and late ventricular filling, peak early to late filling ratio showed only a small change during PTCA. Global systolic function measured on subsequent inflations during PTCA using 2-dimensional echocardiography showed ejection fraction decreased from 62 ± 6% to 35 ± 7% ($p < 0.0005$) during left anterior descending coronary artery PTCA and correlated highly with the mean percent decrease in early peak filling rate ($r = 0.95$). We conclude that during acute ischemia there are marked abnormalities in both early and late ventricular filling that are paralleled by a commensurate decrease in systolic function. There is also a decrease in atrial stroke volume during coronary occlusion that may be due to atrial pump failure induced by atrial afterload mismatch.

546 Early and Late Assessment of Stenosis Geometry After Coronary Arterial Stenting

Jacques Puel, Yves Juilliere, Michel E. Bertrand, Anthony F. Rickards, Ulrich Sigwart, and Patrick W. Serruys

This study assessed early and late modifications in stenosis geometry after stenting of coronary arteries. Quantitative coronary angiography was performed in 11 patients (mean age 55 years) with single coronary artery stenosis. Immediately following stent implantation, an additional increase in minimal luminal cross-sectional area of the dilated vessel was observed, suggesting that the self-expanding stainless-steel endoprosthesis used in this study had a dilating function. After a 3-month follow-up, neointimal poliferation was the likely cause of a small diffuse narrowing of the stented artery without hemodynamic repercussions. Whether this was a progressive process leading to important restenosis at long-term follow-up is unknown. Stenting of coronary arteries is a potentially valuable technique for preventing both abrupt closure and late restenosis.

ONE SIMPLE
THERAPEUTIC DECISION
SETS IN MOTION A LIFETIME
OF BENEFITS.

ONE TABLET A DAY
TENORMIN®
(atenolol)

SIMPLE TO START WITH.
BETTER TO STAY WITH.

See adjacent page for brief summary of prescribing information.

CARDIOSELECTIVE*
HYDROPHILIC

ONE TABLET A DAY

TENORMIN®
(atenolol)

SIMPLE TO START WITH.
BETTER TO STAY WITH.

A beta$_1$-selective (cardioselective) blocking agent.

DESCRIPTION: TENORMIN (atenolol), a synthetic, beta$_1$-selective (cardioselective) adrenoreceptor blocking agent, may be chemically described as benzeneacetamide, 4-[2′-hydroxy-3′-[(1 methylethyl) amino] propoxy]-. Atenolol (free base) has a molecular weight of 266. It is a relatively polar hydrophilic compound with a water solubility of 26.5 mg/mL at 37°C and a log partition coefficient (octanol/water) of 0.23. It is freely soluble in 1N HCl (300 mg/mL at 25°C) and less soluble in chloroform (3 mg/mL at 25°C).

TENORMIN is available as 50 mg and 100 mg tablets for oral administration.

Inactive Ingredients: magnesium stearate, microcrystalline cellulose, povidone, sodium starch glycolate.

INDICATIONS AND USAGE: Hypertension: TENORMIN is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide-type diuretic.

Angina Pectoris Due to Coronary Atherosclerosis: TENORMIN is indicated for the long-term management of patients with angina pectoris.

CONTRAINDICATIONS: TENORMIN is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure. (See WARNINGS.)

WARNINGS: Cardiac Failure: Sympathetic stimulation is necessary in supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, TENORMIN should be administered cautiously. Both digitalis and atenolol slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic and the response observed closely. If cardiac failure continues despite adequate digitalization and diuresis, TENORMIN should be withdrawn. (See Dosage and Administration.)

Cessation of Therapy With TENORMIN: Patients with coronary artery disease, who are being treated with TENORMIN, should be advised against abrupt discontinuation of therapy. Severe exacerbation of angina and the occurrence of myocardial infarction and ventricular arrhythmias have been reported in angina patients following the abrupt discontinuation of therapy with other beta blockers. The last two complications may occur with or without preceding exacerbation of the angina pectoris. To date, there has been no report of myocardial infarction or severe angina upon withdrawal of TENORMIN, probably due to its long plasma half-life. Because of the problems encountered with other beta blockers, when discontinuation of TENORMIN is planned, the patients should be carefully observed and advised to limit physical activity to a minimum. If the angina worsens or acute coronary insufficiency develops, it is recommended that TENORMIN be promptly reinstituted, at least temporarily. (See Dosage and Administration.)

Bronchospastic Diseases: PATIENTS WITH BRONCHOSPASTIC DISEASE SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, TENORMIN may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, the lowest possible dose of TENORMIN should be used with therapy initiated at 50 mg, and a beta$_2$-stimulating agent (bronchodilator) should be made available. If dosage must be increased, dividing the dose should be considered in order to achieve lower peak blood levels.

Anesthesia and Major Surgery: As with all beta-receptor blocking drugs it may be decided to withdraw TENORMIN before surgery. In this case, 48 hours should be allowed to elapse between the last dose and anesthesia. If treatment is continued, care should be taken when using anesthetic agents which depress the myocardium such as ether, cyclopropane, and trichloroethylene.

TENORMIN, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects on the heart can be reversed by administration of such agents (eg, dobutamine or isoproterenol with caution—see section on Overdosage). Manifestations of excessive vagal tone (eg, profound bradycardia, hypotension) may be corrected with atropine (1-2 mg IV).

Diabetes and Hypoglycemia: TENORMIN should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected. TENORMIN does not potentiate insulin-induced hypoglycemia and, unlike nonselective beta blockers, does not delay recovery of blood glucose to normal levels.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (eg, tachycardia) of hyperthyroidism. Abrupt withdrawal of beta blockade might precipitate a thyroid storm; therefore, patients suspected of developing thyrotoxicosis from whom TENORMIN therapy is to be withdrawn should be monitored closely. (See Dosage and Administration.)

PRECAUTIONS: Impaired Renal Function: The drug should be used with caution in patients with impaired renal function. (See Dosage and Administration.)

Drug Interactions: Catecholamine-depleting drugs (eg, reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with TENORMIN plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Should it be decided to discontinue therapy in patients receiving beta blockers and clonidine concurrently, the beta blocker should be discontinued several days before the gradual withdrawal of clonidine.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Two long-term (maximum dosing duration of 18 or 24 months) rat studies and one long-term (maximum dosing duration of 18 months) mouse study, each employing dose levels as high as 300 mg/kg/day or 150 times the maximum recommended human dose, did not indicate a carcinogenic potential in rodents. Results of various mutagenicity studies support this finding.

Fertility of male or female rats (evaluated at dose levels as high as 200 mg/kg/day or 100 times the maximum recommended human dose) was unaffected by atenolol administration.

Animal Toxicology: Chronic studies performed in animals have revealed the occurrence of vacuolation of epithelial cells of Brunner's glands in the duodenum of both male and female dogs at all tested dose levels of atenolol (starting at 15 mg/kg/day or 7.5 times the maximum recommended human dose), and increased incidence of atrial degeneration of hearts of male rats at 300 mg but not 150 mg atenolol/kg/day (150 and 75 times the maximum recommended human dose, respectively).

USAGE IN PREGNANCY: Pregnancy Category C. Atenolol has been shown to produce a dose-related increase in embryo/fetal resorptions in rats at doses equal to or greater than 50 mg/kg/day or 25 or more times the maximum recommended human dose. Although similar effects were not seen in rabbits, the compound was not evaluated in rabbits at doses above 25 mg/kg/day or 12.5 times the maximum recommended human dose. There are no adequate and well-controlled studies in pregnant women. TENORMIN should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Atenolol is excreted in human breast milk at a ratio of 1.5 to 6.8 when compared to the concentration in plasma. Caution should be exercised when TENORMIN is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient. Frequency estimates were derived from controlled studies in which adverse reactions were either volunteered by the patient (US studies) or elicited, eg, by checklist (foreign studies). The reported frequency of elicited adverse effects was higher for both TENORMIN (atenolol) and placebo-treated patients than when these reactions were volunteered. Where frequency of adverse effects for TENORMIN and placebo is similar, causal relationship is uncertain.

The following adverse-reaction data present frequency estimates in terms of percentages: first from the US studies (volunteered side effects) and then from both US and foreign studies (volunteered and elicited side effects):

US STUDIES (% ATENOLOL-% PLACEBO):

CARDIOVASCULAR: bradycardia (3%-0%), cold extremities (0%-0.5%), postural hypotension (2%-1%), leg pain (0%-0.5%)

CENTRAL NERVOUS SYSTEM/NEUROMUSCULAR: dizziness (4%-1%), vertigo (2%-0.5%), lightheadedness (1%-0%), tiredness (0.6%-0.5%), fatigue (3%-1%), lethargy (1%-0%), drowsiness (0.6%-0%), depression (0.6%-0.5%), dreaming (0%-0%)

GASTROINTESTINAL: diarrhea (2%-0%), nausea (4%-1%)

RESPIRATORY (See WARNINGS): wheeziness (0%-0%), dyspnea (0.6%-1%)

TOTALS US AND FOREIGN STUDIES:

CARDIOVASCULAR: bradycardia (3%-0%), cold extremities (12%-5%), postural hypotension (4%-5%), leg pain (3%-1%)

CENTRAL NERVOUS SYSTEM/NEUROMUSCULAR: dizziness (13%-6%), vertigo (2%-0.2%), lightheadedness (3%-0.7%), tiredness (26%-13%), fatigue (6%-5%), lethargy (3%-0.7%), drowsiness (2%-0.5%), depression (12%-9%), dreaming (3%-1%)

GASTROINTESTINAL: diarrhea (3%-2%), nausea (3%-1%)

RESPIRATORY (see WARNINGS): wheeziness (3%-3%), dyspnea (6%-4%)

MISCELLANEOUS: There have been reports of skin rashes and/or dry eyes associated with the use of beta-adrenergic blocking drugs. The reported incidence is small and, in most cases, the symptoms have cleared when treatment was withdrawn. Discontinuance of the drug should be considered if any such reaction is not otherwise explicable. Patients should be closely monitored following cessation of therapy.

POTENTIAL ADVERSE EFFECTS: In addition, a variety of adverse effects have been reported with other beta-adrenergic blocking agents, and may be considered potential adverse effects of TENORMIN.

HEMATOLOGIC: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

ALLERGIC: Fever, combined with aching and sore throat, laryngospasm, and respiratory distress.

CENTRAL NERVOUS SYSTEM: Reversible mental depression progressing to catatonia, visual disturbances, hallucinations, an acute reversible syndrome characterized by disorientation of time and place, short-term memory loss, emotional lability with slightly clouded sensorium, decreased performance on neuropsychometrics.

GASTROINTESTINAL: Mesenteric arterial thrombosis, ischemic colitis.

OTHER: Reversible alopecia, Peyronie's disease, erythematous rash, Raynaud's phenomenon.

MISCELLANEOUS: The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with TENORMIN during investigational use and foreign marketing experience. Furthermore, a number of patients who had previously demonstrated established practolol reactions were transferred to TENORMIN therapy with subsequent resolution or quiescence of the reaction.

OVERDOSAGE: To date, there is no known case of acute overdosage, and no specific information on emergency treatment of overdosage is available. The most common effects expected with overdosage of a beta-adrenergic blocking agent are bradycardia, congestive heart failure, hypotension, bronchospasm, and hypoglycemia.

In the case of overdosage, treatment with TENORMIN should be stopped and the patient carefully observed. TENORMIN can be removed from the general circulation by hemodialysis. In addition to gastric lavage, the following therapeutic measures are suggested if warranted:

BRADYCARDIA: Atropine or another anticholinergic drug.

HEART BLOCK (SECOND OR THIRD DEGREE): Isoproterenol or transvenous cardiac pacemaker.

CONGESTIVE HEART FAILURE: Conventional therapy.

HYPOTENSION (DEPENDING ON ASSOCIATED FACTORS): Epinephrine rather than isoproterenol or norepinephrine may be useful in addition to atropine and digitalis.

BRONCHOSPASM: Aminophylline, isoproterenol, or atropine.

HYPOGLYCEMIA: Intravenous glucose.

DOSAGE AND ADMINISTRATION: Hypertension: The initial dose of TENORMIN is 50 mg given as one tablet a day either alone or added to diuretic therapy. The full effect of this dose will usually be seen within 1 to 2 weeks. If an optimal response is not achieved, the dosage should be increased to TENORMIN 100 mg given as one tablet a day. Increasing the dosage beyond 100 mg a day is unlikely to produce any further benefit.

TENORMIN may be used alone or concomitantly with other antihypertensive agents including thiazide-type diuretics, hydralazine, prazosin, and alpha-methyldopa.

Angina Pectoris: The initial dose of TENORMIN is 50 mg given as one tablet a day. If an optimal response is not achieved within 1 week, the dosage should be increased to TENORMIN 100 mg given as one tablet a day. Some patients may require a dosage of 200 mg once a day for optimal effect.

Twenty-four hour control with once-daily dosing is achieved by giving doses larger than necessary to achieve an immediate maximum effect. The maximum early effect on exercise tolerance occurs with doses of 50 to 100 mg, but at these doses the effect at 24 hours is attenuated, averaging about 50% to 75% of that observed with once-a-day oral doses of 200 mg.

Patients with Renal Impairment: Since TENORMIN is excreted via the kidneys, dosage should be adjusted in cases of severe impairment of renal function. No significant accumulation of TENORMIN occurs until creatinine clearance falls below 35 mL/min/1.73 m2 (normal range is 100-150 mL/min/1.73 m2); therefore, the following maximum dosages are recommended for patients with renal impairment:

Creatinine Clearance (mL/min/1.73 m2)	Atenolol Elimination Half-life (h)	Maximum Dosage
15-35	16-27	50 mg daily
<15	>27	50 mg every other day

Patients on hemodialysis should be given 50 mg after each dialysis; this should be done under hospital supervision as marked falls in blood pressure can occur.

Cessation of Therapy: If withdrawal of TENORMIN therapy is planned, it should be achieved gradually over a period of about 2 weeks. Patients should be carefully observed and advised to limit physical activity to a minimum.

HOW SUPPLIED: Tablets of 50 mg atenolol, NDC 0310-0105 (round, flat, uncoated white tablets identified with ICI debossed on one side and 105 debossed on the other side, bisected) are supplied in bottles of 100 tablets and unit-dose packages of 100 tablets.

Tablets of 100 mg atenolol, NDC 0310-0101 (round, flat, uncoated white tablets identified with ICI debossed on one side and 101 debossed on the other side) are supplied in bottles of 100 tablets and unit-dose packages of 100 tablets.

Protect from heat, light, and moisture.

A/11/86

*Cardioselectivity denotes a relative preference for β_1-receptors, located chiefly in cardiac tissue. This preference is not absolute.

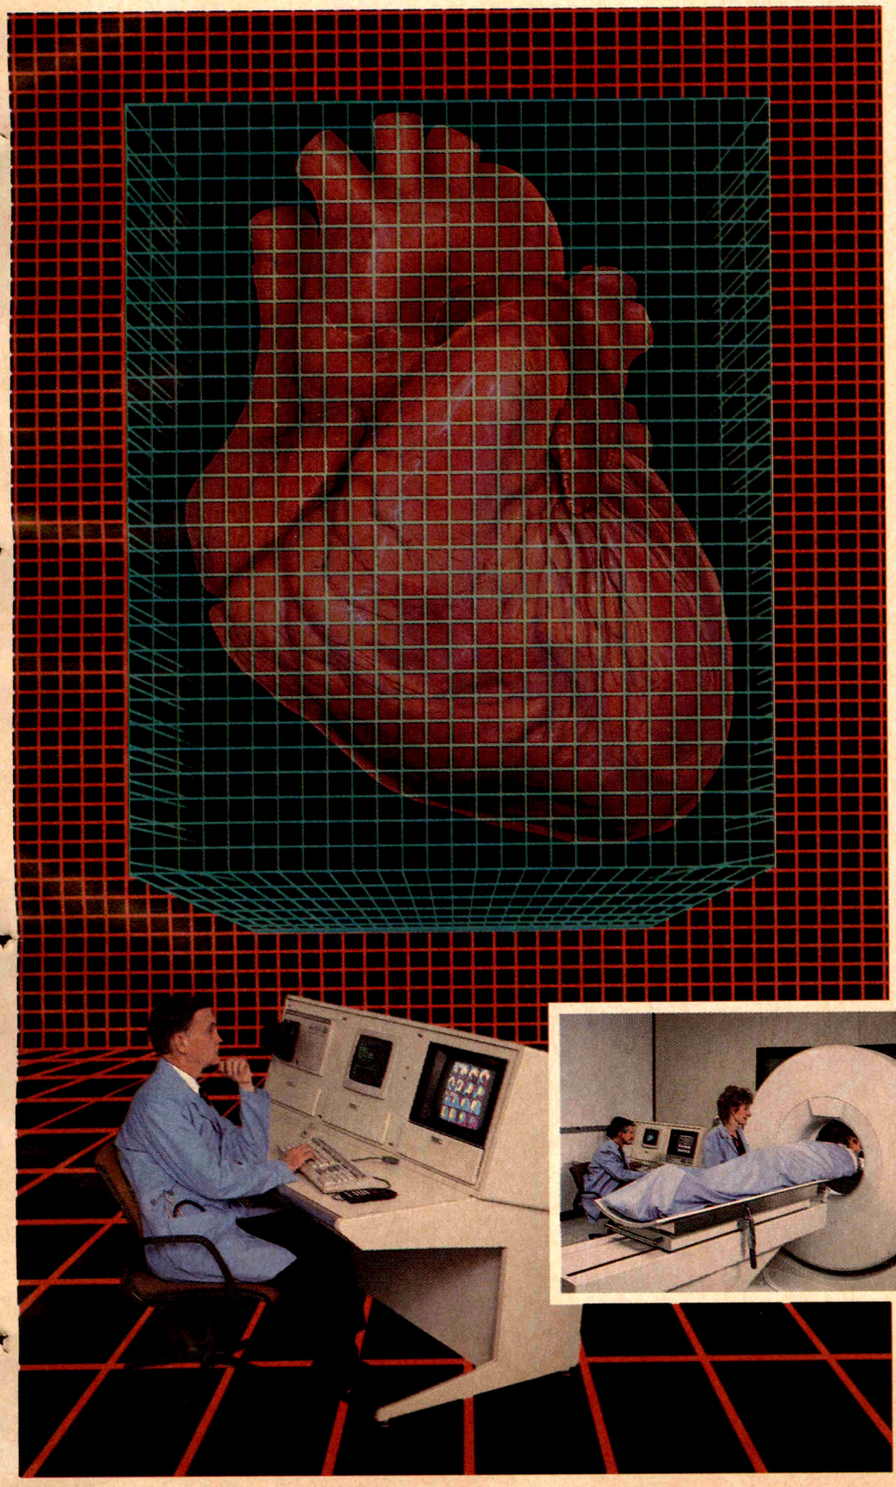
POSICAM™: The most powerful imaging in Cardiology!



The POSICAM™ SYSTEM, from Positron Corporation means accurate, non-invasive diagnosis of coronary artery disease by routine clinical positron emission tomography. POSICAM™ provides high-speed, high resolution imaging using uniform 3-dimensional volumetric sampling, without data gaps between image planes. Twenty-one simultaneous overlapping slices of the whole heart in short axis, long axis, or angled views create the first and only true 3-dimensional pictures of cardiac perfusion, metabolism, and function.

User-friendly software, validated in over 700 clinical studies, gives unsurpassed throughput and data analysis. POSICAM™ is the only camera design tested in large clinical trials with generator-produced Rubidium-82 for cardiac imaging without a cyclotron. This revolutionary imaging system is now affordable for hospitals and clinics to provide the most advanced cardiac care for their patients.

Innovation and reliability for serious medical decisions that affect lives.

Positron has made the commitment.

554 Intraaortic Balloon Pumping for Prolonged Circulatory Support

Paul S. Freed, Tarik Wasfie, Barina Zado, and Adrian Kantrowitz

Of 733 patients who received an intraaortic balloon pump between 1967 and 1982, 27 were supported for 20 days or more (range 20 to 71 days). Complications, including vascular compromise (37%), infections (67%) and bleeding (26%), were significantly more frequent in the prolonged-support patient than in those assisted <20 days (15%, $p = 0.001$; 25%, $p = 0.0001$; and 15%, $p = 0.04$, respectively). Survival rates of the 2 groups were similar: 63% in the prolonged-support group and 57% among controls ($p = 0.5$). Of 17 prolonged-support patients discharged from the hospital, 9 died within 6 months and 8 survived >2 years. No patient with chronic congestive heart failure ever became a long-term survivor. Prolonged intraaortic balloon pumping support in chronic congestive heart failure patients lacking surgically correctable lesions can extend life while arrangements for definitive therapy are made (transplant, permanent mechanical assistance). Where definitive therapy is unavailable, intraaortic balloon pumping may provide additional months of life.

558 Risks Associated With Intraaortic Balloon Pumping in Patients With and Without Diabetes Mellitus

Tarik Wasfie, Paul S. Freed, Melvyn Rubenfire, Waldemar Wajszczuk, Paula Reimann, Witold Brozyna, M. Anthony Schork, Jay Kozlowski, and Adrian Kantrowitz

Between 1967 and 1982, intraaortic balloon pumping (IABP) was attempted in 733 patients. Of those, 132 were diabetic: 51 patients were managed with diet alone, 46 took oral hypoglycemic agents and 35 patients needed insulin. Vascular complications associated with IABP occurred in 34% of the insulin-dependent diabetics, 18% of other diabetics and 14% of nondiabetics. Infectious complications were 37, 22 and 25%, respectively. Seventy-five diabetic patients (57%) were discharged alive from the hospital after balloon pumping, essentially the same proportion as among nondiabetic patients (58%). We conclude that although diabetics incur a higher complication rate, IABP is not contraindicated.

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

563 QRS Morphology-Dependent Pharmacodynamics in Multiform Ventricular Ectopic Activity

Kenneth M. Kessler, Daneil McAuliffe, Patricia Kozlovskis, Richard G. Trohman, Liaqat Zaman, Agustin Castellanos, Rafael Sequeira, and Robert J. Myerburg

The effect of an infusion of intravenous procainamide on the frequency of ventricular premature complexes (VPCs) of differing QRS morphologies was studied in 20 patients with multiform ectopic activity. In 8 patients, VPCs of the most frequent QRS morphology remained suppressed at lower procainamide concentrations and for longer times than did VPCs of

Please see adjacent page for brief summary.

QUINIDEX
EXTENTABS®
(Quinidine Sulfate, USP)

The following is a brief summary only. Before prescribing, see complete prescribing information in Quinidex product labeling.

Contraindications: Intraventricular conduction defects. Complete A-V block. A-V conduction disorders caused by digitalis intoxication. Aberrant impulses and abnormal rhythms due to escape mechanisms. Idiosyncrasy or hypersensitivity to quinidine or related cinchona derivatives. Myasthenia gravis.

Warnings: In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio, resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine.

Reports in the literature indicate that serum concentrations of digoxin may increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored for digitalis toxicity. Reduction of digoxin dosage may have to be considered.

Manifestations of quinidine cardiotoxicity such as excessive prolongation of the QT interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring.

In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function manifested by hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals.

Quinidine should be used with extreme caution in patients with incomplete AV block since complete AV block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication.

Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in serum, leading to toxicity.

Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or serum levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal.

Cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4–8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.

Precautions: *General*—All the precautions applying to regular quinidine therapy apply to this product. Hypersensitivity or anaphylactoid reactions to quinidine, although rare, should be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and determination of serum quinidine levels are indicated when large doses of quinidine are used or with patients who present an increased risk.

Information for Patients—As with all solid dosage medications, Quinidex Extentabs should be taken with an adequate amount of fluid, preferably with the patient in an upright position to facilitate swallowing. They should be swallowed whole in order to preserve the controlled-release mechanism.

Laboratory Tests—Periodic blood counts and liver and kidney function tests should be performed during long-term therapy; the drug should be discontinued if blood dyscrasias or evidence of hepatic or renal dysfunction occurs.

Drug Interactions

Drug	Effect
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
Quinidine with digoxin	Increased serum concentration of digoxin (See Warnings)
Quinidine with amiodarone	Increased serum concentration of quinidine
Quinidine with cimetidine	Prolonged quinidine half-life and an increase in serum quinidine level
Quinidine with ranitidine	Premature ventricular contractions and/or bigeminy
Quinidine with verapamil	Increased quinidine half-life and an increase in serum quinidine level; potential hypotensive reactions
Quinidine with nifedipine	Decreased serum concentrations of quinidine

Carcinogenesis: Studies in animals have not been performed to evaluate the carcinogenic potential of quinidine.

Pregnancy, Teratogenic Effects: Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinidex Extentabs should be administered to a pregnant woman only if clearly indicated.

Nonteratogenic Effects: Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.

Labor and Delivery—There is no known use for Quinidex Extentabs in labor and delivery. However, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.

Nursing Mothers—Because of passage of the drug into breast milk, caution should be exercised when Quinidex Extentabs are administered to a nursing woman.

Pediatric Use—There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinidex Extentabs in children.

Adverse Reactions: Symptoms of cinchonism, such as ringing in the ears, loss of hearing, dizziness, lightheadedness, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal.

Gastrointestinal—Nausea, vomiting, abdominal pain, diarrhea, anorexia, granulomatous hepatitis (which may be preceded by fever), esophagitis.

Cardiovascular—Ventricular extrasystoles occurring at a rate of one or more every 6 normal beats; widening of the QRS complex and prolonged QT interval; complete A-V block; ventricular tachycardia and fibrillation; ventricular flutter; torsade de pointes; arterial embolism; hypotension; syncope.

Central Nervous System—Headache, vertigo, apprehension, excitement, confusion, delirium, dementia, ataxia, depression.

Ophthalmologic and Otologic—Disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, photophobia, diplopia, night blindness, scotomata), optic neuritis, reduced visual field.

Dermatologic—Cutaneous flushing with intense pruritus, photosensitivity, urticaria, rash, eczema, exfoliative eruptions, psoriasis, abnormalities of pigmentation.

Hypersensitivity—Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatotoxicity, granulomatous hepatitis (See Warnings), purpura, vasculitis.

Hematologic—Thrombocytopenia, thrombocytopenic purpura, agranulocytosis, acute hemolytic anemia, hypoprothrombinemia, leukocytosis, shift to left in WBC differential, neutropenia.

Immunologic—Systemic lupus erythematosus, lupus nephritis.

Miscellaneous—Fever, increase in serum skeletal muscle creatine phosphokinase, arthralgia, myalgia.

CLASSIFIED

CARDIOLOGIST—The University of California, San Francisco and the Central California Faculty Medical Group seek a staff cardiologist to join the teaching faculty at their affiliate, Valley Medical Center of Fresno. Applicants should be board certified or eligible. The scope of practice at VMC includes full invasive and non-invasive cardiology services. Geographic location offers a large population with a variety of cardiological diseases. VMC has 350 active beds and conducts residency training programs in most major clinical disciplines. The central California location offers enjoyable and affordable California living. Competitive salary and benefits. UCSF is an equal opportunity employer. Address inquiries to: Lauren Grayson, M.D., Chief of Cardiology, CCFMG, 2212 N. Winery, #130, Fresno, CA 93703, (209) 252-1835.

MILWAUKEE AREA: CARDIOLOGIST BC/BE for invasive and non-invasive practice. Rapidly expanding Cardiology Department has an immediate opening for a third Cardiologist to join the staff of a 55 physician multispecialty clinic located in a suburban setting within 20 minutes of downtown Milwaukee. Excellent salary and fringe benefits. Submit CV to Administrator, P.O. Box 427, Menomonee Falls, WI 53051 (Equal Opportunity Employer).

CAREER CHANGE OPPORTUNITIES in the Pharmaceutical Industry. We have assignments for experienced board certified/eligible physicians. Send your CV to Bruce Rogers Co., Management Consultants, 20 Main Street, Port Washington, NY 11050, (516) 883-1058.

Specialize in Success.

Join a successful operation. . .The Southern California Permanente Medical Group. We are a well-established multispecialty group practice. Our partnership is comprised of and managed by SCPMG physicians.

We have immediate opportunities available at the Kaiser Permanente Medical Centers in **Riverside** and **Fontana** for board eligible/certified **Cardiologists.**

Fontana and Riverside are part of Southern California's Inland Empire—one of the fastest growing areas in the country. Affordable housing, major educational and cultural institutions, famous mountain and desert resorts are all to be found in this scenic location.

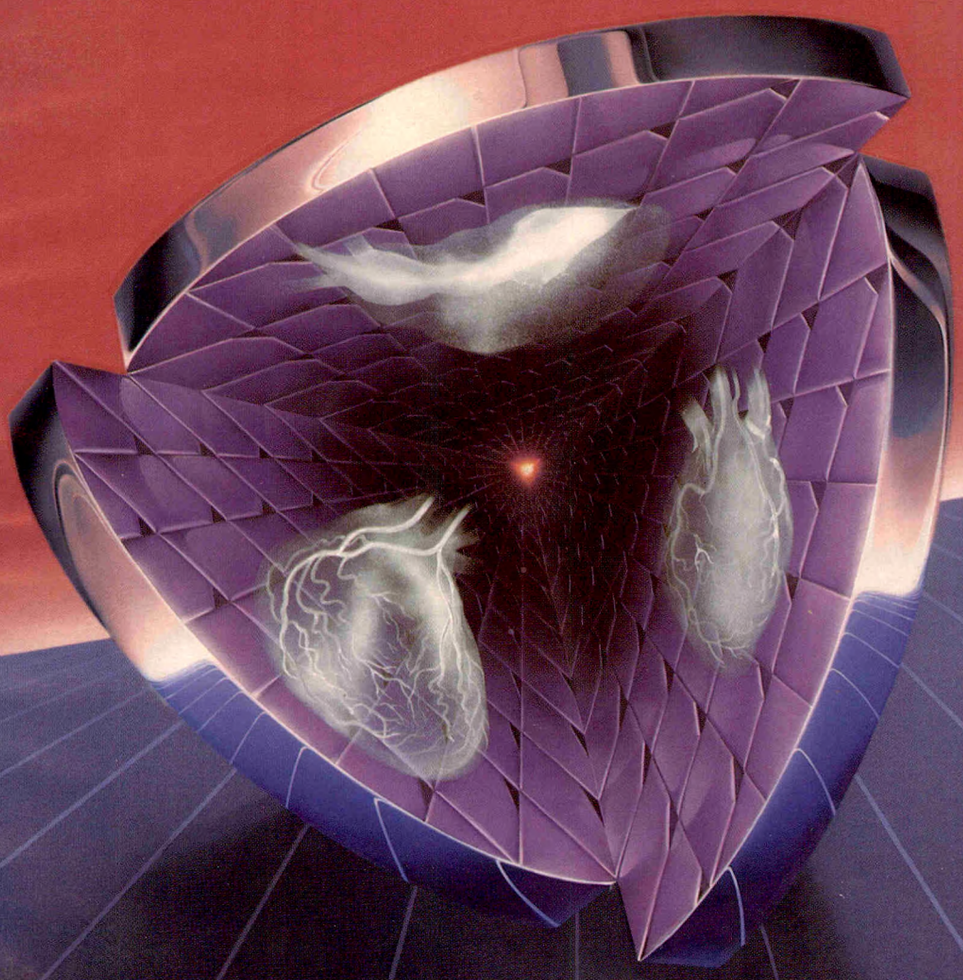
Our compensation is competitive and benefits are outstanding. They include: professional liability, medical and dental coverage, vacation and sick leave, continuing education, life insurance and retirement plans. **After two years full-time employment, physicians are eligible to be considered for partnership.**

For a physician application, please call (818) 405-3224 or write to: Physician Recruitment, Dept. 29EI8, Walnut Center, Pasadena, CA 91188-8854.

Equal Opportunity Employer M/F/H

KAISER PERMANENTE
Good People. Good Medicine.

The image of safety.

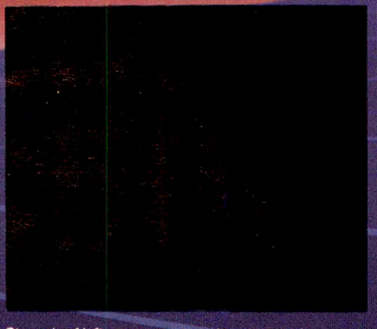


The image of safety in angiocardiography.

In angiocardiography, you ask a lot of the contrast agent you use.

Safety.
Imaging performance.
Patient comfort and tolerance.

Experience with OMNIPAQUE in clinical use and trials continues to demonstrate its unique combination of lowest chemotoxicity and low osmolality, providing the best of all three.



Stenosis of left coronary artery demonstrated with OMNIPAQUE.

NONIONIC

OMNIPAQUE®

(IOHEXOL)

An ongoing record of safety in angiocardiography.

See next page for important product information concerning contraindications, warnings, adverse reactions, patient selection, and prescribing and precautionary recommendations.

OMNIPAQUE® 240 300 350

INJECTION (IOHEXOL) INTRAVASCULAR

PLEASE CONSULT FULL PRODUCT INFORMATION BEFORE USING. A SUMMARY FOLLOWS:

DESCRIPTION: OMNIPAQUE is a nonionic, water-soluble radiographic contrast medium for intravascular administration in concentrations of 240, 300, and 350 mgI/mL. Each milliliter of iohexol solution contains 1.21 mg tromethamine and 0.1 mg edetate calcium disodium with the pH adjusted between 6.8 and 7.7 with hydrochloric acid or sodium hydroxide, but it contains no preservatives.

CONTRAINDICATIONS: OMNIPAQUE should not be administered to patients with a known hypersensitivity to iohexol.

WARNINGS: OMNIPAQUE should be used with extreme care in patients with severely impaired renal and/or hepatic function; severe thyrotoxicosis, hyperthyroidism, or an autonomously functioning thyroid nodule; diabetes with a serum creatinine level above 3 mg/dL. It is not recommended for use in patients with anuria.

Patients with known or suspected pheochromocytoma should receive a minimum of contrast medium if the benefit of the examination is judged to outweigh its risk; blood pressure should be monitored throughout the procedure, and measures for the treatment of hypertensive crisis should be readily available.

Contrast agents are potentially hazardous in patients with multiple myeloma or other paraproteinemia, particularly those with therapeutically resistant anuria. The combination of contrast agent and dehydration may precipitate myeloma protein in the renal tubules. No form of therapy, including dialysis, has been successful in reversing the effect. Myeloma, which occurs most commonly in persons over age 40, should be considered before instituting intravascular administration of contrast agents.

Ionic contrast media, when injected intravenously or intra-arterially, may promote sickling in individuals who are homozygous for sickle cell disease.

PRECAUTIONS: Diagnostic procedures that involve the use of radiopaque diagnostic agents should be carried out under the direction of personnel with the prerequisite training and with a thorough knowledge of the particular procedure to be performed. Appropriate facilities should be available for coping with any complication of the procedure, as well as for emergency treatment of severe reactions to the contrast agent itself. Competent personnel and emergency facilities should be available, since severe delayed reactions have been reported (see ADVERSE REACTIONS). The possibility of serious, life-threatening, fatal, anaphylactoid, or cardiovascular reactions should always be considered (see ADVERSE REACTIONS). It is of utmost importance that a course of action be carefully planned in advance for immediate treatment of serious reactions. Preparatory dehydration is dangerous and may contribute to acute renal failure in patients with: advanced vascular disease, in diabetic patients, and in susceptible nondiabetic patients (often elderly with preexisting renal disease). *Patients should be well hydrated prior to and following iohexol administration.* Careful consideration of the potential risk of acute renal failure should be given before performing excretory urography in diabetic patients with diabetic nephropathy and in susceptible nondiabetic patients (often elderly with preexisting renal disease). Immediately following surgery, excretory urography should be used with caution in renal transplant recipients. The possibility of an idiosyncratic reaction in susceptible patients should always be considered (see ADVERSE REACTIONS). The susceptible population includes, but is not limited to, patients with a history of a previous reaction to contrast media, patients with a known sensitivity to iodine per se, and patients with a known clinical hypersensitivity: bronchial asthma, hay fever, and food allergies. A thorough medical history with emphasis on allergy and hypersensitivity, prior to the injection of any contrast media, may be more accurate than pretesting in predicting potential adverse reactions.

A positive history of allergies or hypersensitivity does not arbitrarily contraindicate the use of a contrast agent where a diagnostic procedure is thought essential, but caution should be exercised (see ADVERSE REACTIONS). Premedication with antihistamines or corticosteroids to avoid or minimize possible allergic reactions in such patients should be considered and administered using separate syringes. Recent reports indicate that such pretreatment does not prevent serious, life-threatening reactions but may reduce both their incidence and severity.

Even though the osmolality of OMNIPAQUE is low compared to diatrizoate- or iothalamate-based ionic agents of comparable iodine concentration, the potential transitory increase in circulatory osmotic load in patients with congestive heart failure requires caution during injection. These patients should be observed for several hours following the procedure to detect delayed hemodynamic disturbances.

General anesthesia may be indicated in the performance of some procedures in selected adult patients; however, a higher incidence of adverse reactions has been reported in these patients and may be attributable to the inability of the patient to identify untoward symptoms or to the hypotensive effect of the anesthesia which can reduce cardiac output and increase the duration of exposure to the contrast agent.

Angiography should be avoided whenever possible in patients with homocystinuria, because of the risk of inducing thrombosis and embolism.

In angiographic procedures, the possibility of dislodging plaques or damaging or perforating the vessel wall should be borne in mind during the catheter manipulations and contrast medium injection. Test injections to ensure proper catheter placement are recommended.

Selective coronary arteriography should be performed only in those patients in whom the expected benefits outweigh the potential risk. The inherent risks of angiocardiography in patients with chronic pulmonary emphysema must be weighed against the necessity for performing this procedure.

When OMNIPAQUE is to be injected using plastic disposable syringes, the contrast medium should be drawn into the syringe and used immediately.

The inhibitory effects of nonionic contrast media on mechanisms of hemostasis have been shown, in vitro, to be less than those of ionic contrast media at comparable concentrations. For this reason, standard angiographic procedures should always be followed: angiographic catheters should be flushed frequently, and prolonged contact of blood with contrast media in syringes and catheters should be avoided.

If nondisposable equipment is used, scrupulous care should be taken to prevent residual contamination with traces of cleansing agents.

Parenteral products should be inspected and discarded if particulate matter or discoloration is present.

Drug/Laboratory Test Interaction: If iodine-containing isotopes are to be administered for the diagnosis of thyroid disease, the iodine-binding capacity of thyroid tissue may be reduced for up to 2 weeks after contrast medium administration. Thyroid function tests which do not depend on iodine estimation, eg, T_3 resin uptake or direct thyroxine assays, are not affected. Many radiopaque contrast agents are incompatible in vitro with some antihistamines and many other drugs; therefore, no other pharmaceuticals should be admixed with contrast agents.

Carcinogenesis, Mutagenesis, Impairment of Fertility: No long-term animal studies have been performed to evaluate carcinogenic potential, mutagenesis, or whether OMNIPAQUE can affect fertility in men or women.

Pregnancy Category B: Reproduction studies have been performed in rats and rabbits with up to 100 times the recommended human dose. No evidence of impaired fertility or harm to the fetus has been demonstrated due to OMNIPAQUE. There are, however, no studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: It is not known to what extent iohexol is excreted in human milk. However, many injectable contrast agents are excreted unchanged in human milk. Although it has not been established that serious adverse reactions occur in nursing infants, caution should be exercised when intravascular contrast media are administered to nursing women. Bottle feedings may be substituted for breast feedings for 24 hours following administration of OMNIPAQUE.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Usually mild to moderate in severity. However, serious, life-threatening, and fatal reactions, mostly of cardiovascular origin, have been associated with the administration of iodine-containing contrast media, including OMNIPAQUE. The injection of contrast media is frequently associated with the sensation of warmth and pain, especially in peripheral angiography; pain and warmth are less frequent and less severe with OMNIPAQUE than with many contrast media.

Cardiovascular System: Arrhythmias including PVCs and PACs (2%), angina/chest pain (1%), and hypotension (0.8%). Others including cardiac failure, asystole, bradycardia, tachycardia, and vasovagal reaction were reported with an individual incidence of less than 0.4%. In controlled clinical trials involving 1,213 patients, one fatality occurred. A cause-and-effect relationship between this death and iohexol has not been established.

Nervous System: Vertigo [including dizziness and lightheadedness] (0.7%), pain (3%), photomas (2%), headache (2%), and taste perversion (1%). Others including anxiety, blurred vision, fever, motor and speech dysfunction, convulsion, paresthesia, somnolence, stiff neck, hemiparesis, and nystagmus were reported, with an individual incidence of less than 0.3%.

Respiratory System: Dyspnea and laryngitis, with an individual incidence of 0.1%.

Gastrointestinal System: Nausea (2%) and vomiting (0.6%). Others including diarrhea, dyspepsia, and dry mouth were reported, with an individual incidence of less than 0.2%.

Skin and Appendages: Urticaria (0.3%) and purpura (0.1%).

General Adverse Reactions to Contrast Media: The following reactions have been reported after administration of other intravascular iodinated contrast media, and rarely with iohexol. *Reactions due to technique:* hematomas and ecchymoses. *Hemodynamic reactions:* vein cramp and thrombophlebitis following intravenous injection. *Cardiovascular reactions:* rare cases of cardiac arrhythmias, reflex tachycardia, chest pain, cyanosis, hypertension, hypotension, peripheral vasodilatation, shock, and cardiac arrest. *Renal reactions:* occasionally, transient proteinuria; rarely, oliguria or anuria. *Allergic reactions:* asthmatic attacks, nasal and conjunctival symptoms, dermal reactions such as urticaria with or without pruritus, as well as pleomorphic rashes, sneezing, and lacrimation; rarely, anaphylactic reactions. Rare fatalities have occurred due to these or unknown causes. *Signs and symptoms related to the respiratory system:* pulmonary or laryngeal edema, bronchospasm, dyspnea; or *to the nervous system:* restlessness, tremors, convulsions. *Other reactions:* flushing, pain, warmth, metallic taste, nausea, vomiting, anxiety, headache, confusion, pallor, weakness, sweating, localized areas of edema (especially facial cramps), neutropenia, and dizziness. Rarely, immediate or delayed rigors can occur, sometimes accompanied by hyperpyrexia. Infrequently, "iodism" (salivary gland swelling) from organic iodinated compounds appears 2 days after exposure and subsides by the sixth day.

In general, the reactions that are known to occur upon parenteral administration of iodinated contrast agents are possible with any nonionic agent. Approximately 95% of adverse reactions accompanying the use of water-soluble intravascularly administered contrast agents are mild to moderate in degree. However, severe, life-threatening anaphylactoid reactions, mostly of cardiovascular origin, have occurred. Reported incidences of death range from 6.6 per 1 million (0.00066%) to 1 in 10,000 (0.01%). Most deaths occur during injection or 5 to 10 minutes later, the main feature being cardiac arrest, with cardiovascular disease as the main aggravating factor. Isolated reports of hypotensive collapse and shock are found in the literature. The incidence of shock is estimated to be 1 out of 20,000 (0.005%) patients.

Adverse reactions to injectable contrast media fall into two categories: chemotoxic reactions and idiosyncratic reactions.

Chemotoxic reactions result from the physicochemical properties of the contrast media, the dose, and the speed of injection. All hemodynamic disturbances and injuries to organs or vessels perfused by the contrast medium are included in this category.

Idiosyncratic reactions include all other reactions. They occur more frequently in patients 20 to 40 years old. Idiosyncratic reactions may or may not be dependent on the amount of dose injected, the speed of injection, and the radiographic procedure. Idiosyncratic reactions are subdivided into minor, intermediate, and severe. The minor reactions are self-limited and of short duration; the severe reactions are life-threatening and treatment is urgent and mandatory.

The reported incidence of adverse reactions to contrast media in patients with a history of allergy is twice that in the general population. Patients with a history of previous reactions to a contrast medium are three times more susceptible than other patients. However, sensitivity to contrast media does not appear to increase with repeated examinations.

Most adverse reactions to injectable contrast media appear within 1 to 3 minutes after the start of injection, but delayed reactions may occur.

Regardless of the contrast agent employed, the overall estimated incidence of serious adverse reactions is higher with angiocardiography than with other procedures. Cardiac decompensation, serious arrhythmias, angina pectoris, or myocardial ischemia or infarction may occur during angiocardiography and left ventriculography. Electrocardiographic and hemodynamic abnormalities occur less frequently with OMNIPAQUE than with diatrizoate meglumine and diatrizoate sodium injection.

OVERDOSAGE: Overdosage may occur. The adverse effects of overdosage are life-threatening and affect mainly the pulmonary and cardiovascular systems. The symptoms include cyanosis, bradycardia, acidosis, pulmonary hemorrhage, convulsions, coma, and cardiac arrest. Treatment of an overdosage is directed toward the support of all vital functions and prompt institution of symptomatic therapy.

The intravenous LD_{50} values of OMNIPAQUE (in grams of iodine per kilogram body weight) are 24.2 in mice and 15.0 in rats.

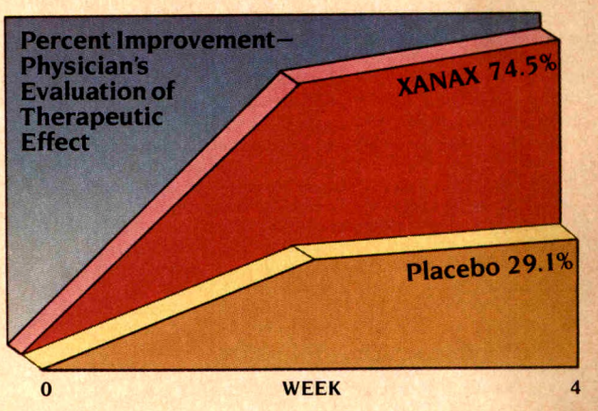
Many anxious patients
have cardiovascular
symptoms of anxiety.

Xanax effectively relieves anxiety...

In double-blind, four-week clinical trials in 976 patients with moderate to severe anxiety, therapy with XANAX was compared with placebo.[1]

XANAX was significantly more effective ($P<0.001$) than placebo in relieving the anxiety, with over half of the patients showing marked to moderate improvement by the first evaluation period (one week).



...including anxiety with associated cardiovascular symptoms...

Most patients in the study had cardiovascular symptoms even though cardiovascular disease was ruled out. XANAX was shown to effectively relieve anxiety with associated cardiovascular symptoms.

...and anxiety with associated depressive symptoms.

Over 70% of these patients experienced moderate to severe depressed mood. XANAX was shown to be significantly more effective ($P<0.014$) than placebo in improving depressed mood.

Please see adjacent page for brief summary of prescribing information.

XANAX® Tablets
(alprazolam) ℞

CONTRAINDICATIONS
Patients with sensitivity to this drug or other benzodiazepines and in acute narrow angle glaucoma.

WARNINGS
Not of value in psychotic patients. Caution patients against hazardous occupations requiring complete mental alertness and about the simultaneous ingestion of alcohol and other CNS depressant drugs.

Benzodiazepines can cause fetal harm in pregnant women. Warn patients of the potential hazard to the fetus. Avoid during the first trimester.

PRECAUTIONS
General: The dosage of XANAX Tablets should be reduced or withdrawn gradually, since withdrawal seizures have been reported upon abrupt withdrawal. If XANAX is combined with other psychotropics or anticonvulsant drugs, consider drug potentiation (see Drug Interaction section). Exercise the usual precautions regarding size of the prescription for depressed or suicidal patients. In elderly and debilitated patients, use the lowest possible dosage (see Dosage and Administration). Observe the usual precautions in treating patients with impaired renal or hepatic function.

Information for Patients: Alert patients about: (a) consumption of alcohol and drugs, (b) possible fetal abnormalities, (c) operating machinery or driving, (d) not increasing dose of the drug due to risk of dependence, (e) not stopping the drug abruptly. *Laboratory Tests*: Not ordinarily required in otherwise healthy patients. *Drug Interactions*: Additive CNS depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol and other CNS depressants. Pharmacokinetic interactions with other drugs, e.g., cimetidine, have been reported. *Drug/Laboratory Test Interactions*: No consistent pattern for a drug or test. *Carcinogenesis, Mutagenesis, Impairment of Fertility*: No carcinogenic potential or impairment of fertility in rats. *Pregnancy*: See Warnings. *Nonteratogenic Effects*: The child born of a mother on benzodiazepines may be at some risk for withdrawal symptoms and neonatal flaccidity. *Labor and Delivery*: No established use. *Nursing Mothers*: Benzodiazepines are excreted in human milk. Women on XANAX should not nurse. *Pediatric Use*: Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS
Side effects are generally observed at the beginning of therapy and usually disappear with continued medication. In the usual patient, the most frequent side effects are likely to be an extension of the pharmacologic activity of XANAX, e.g., drowsiness or lightheadedness.

Central nervous system: Drowsiness, lightheadedness, depression, headache, confusion, insomnia, nervousness, syncope, dizziness, akathisia, and tiredness/sleepiness. *Gastrointestinal*: Dry mouth, constipation, diarrhea, nausea/vomiting, and increased salivation. *Cardiovascular*: Tachycardia/palpitations, and hypotension. *Sensory*: Blurred vision. *Musculoskeletal*: Rigidity and tremor. *Cutaneous*: Dermatitis/allergy. *Other side effects*: Nasal congestion, weight gain, and weight loss.

Withdrawal seizures have been reported upon rapid decrease or abrupt discontinuation of XANAX. (See Precautions.)

In addition, the following adverse events have been reported with the use of benzodiazepines: dystonia, irritability, concentration difficulties, anorexia, transient amnesia or memory impairment, loss of coordination, fatigue, sedation, slurred speech, jaundice, musculoskeletal weakness, pruritus, diplopia, dysarthria, changes in libido, menstrual irregularities, incontinence and urinary retention.

Paradoxical reactions such as stimulation, agitation, increased muscle spasticity, sleep disturbances, and hallucinations may occur. Should these occur, discontinue the drug.

During prolonged treatment, periodic blood counts, urinalysis, and blood chemistry analysis are advisable. Minor EEG changes, of unknown significance, have been observed.

DRUG ABUSE AND DEPENDENCE
Physical and Psychological Dependence: Withdrawal symptoms have occurred following abrupt discontinuance of benzodiazepines. Withdrawal seizures have occurred upon rapid decrease or abrupt discontinuation of therapy. In all patients, dosage should be gradually tapered under close supervision. Patients with a history of seizures or epilepsy should not be abruptly withdrawn from XANAX. Addiction-prone individuals should be under careful surveillance. *Controlled Substance Class*: XANAX is a controlled substance and has been assigned to schedule IV.

OVERDOSAGE
Manifestations include somnolence, confusion, impaired coordination, diminished reflexes and coma. No delayed reactions have been reported.

DOSAGE AND ADMINISTRATION
Dosage should be individualized.

The usual starting dose is 0.25 to 0.5 mg, t.i.d. Maximum total daily dose is 4 mg. In the elderly or debilitated, the usual starting dose is 0.25 mg, two or three times daily. Reduce dosage gradually when terminating therapy, by no more than 0.5 milligram every three days.

HOW SUPPLIED
XANAX Tablets are available as 0.25 mg, 0.5 mg, and 1 mg tablets.

Caution: Federal law prohibits dispensing without prescription. B-5-S

SQUIBB DIAGNOSTICS, INC.

the second most frequent QRS morphology (escape procainamide concentration = 2.8 ± 1.7 versus 5.4 ± 2.3 μg/ml, $p < 0.025$; time to escape, 244 ± 138 versus 98 ± 114 min; $p < 0.05$). In 9 other patients, VPCs of the second most frequent QRS morphology remained suppressed at lower procainamide concentrations and for longer times than did VPCs of the most frequent QRS morphology (escape procainamide concentration 2.9 ± 1.4 versus 8.3 ± 6.3 μg/ml, $p < 0.025$; time to escape 317 ± 114 versus 63 ± 80 min; $p < 0.001$). There is apparently a differential pharmacologic effect of procainamide on the foci or pathways responsible for the different QRS morphologies of multiform VPCs.

570 Tocainide Plus Quinidine for Treatment of Ventricular Arrhythmias

Jean T. Barbey, Katherine A. Thompson, Debra S. Echt, Raymond L. Woosley, and Dan M. Roden

Tocainide and quinidine were administered both as single agents and in combination to 14 patients with chronic ventricular arrhythmias. Therapy with tocainide was limited by the occurrence of dose-related adverse reactions in 8 patients, but could be titrated to a dose that was well tolerated in 13 of 14 and effective in 2 of 13. The addition of quinidine gluconate to the tolerated dose of tocainide increased the number of patients with arrhythmia suppression from 2 to 6. After tocainide washout, quinidine alone suppressed arrhythmias in only 3 patients. Analysis of electrocardiogram intervals showed that the drugs had additive effects on the coupling interval of the sinus beat to the predominant ectopic beat, but exerted antagonistic effects on the corrected QT interval. These findings suggest that the combination may be clinically useful, exerting pharmacologic effects unlike either agent alone.

574 Termination of Sustained Ventricular Tachycardia by External Noninvasive Pacing

Jerry C. Luck, Blair P. Grubb, Stephen E. Artman, Robert T. Steckbeck, and Michael L. Markel

Cardiac pacing is useful in the termination of sustained ventricular tachycardia (VT). External noninvasive temporary pacing was compared with endocardial burst ventricular pacing for the termination of sustained VT. External burst pacing terminated 14 of 16 VT morphologies (88%) when compared with endocardial burst termination. The average VT rate terminated by external burst pacing was 163 beats/min (range 125 to 200). These preliminary observations suggest that external burst pacing may be an effective means of terminating some sustained VTs.

578 Prognostic Significance of Arrhythmia Inducibility or Noninducibility at Initial Electrophysiologic Study in Survivors of Cardiac Arrest

Roger A. Freedman, Charles D. Swerdlow, Vivian Soderholm-Difatte, and Jay W. Mason

The value of arrhythmia inducibility or noninducibility at initial electrophysiologic study to predict the likelihood of arrhythmia recurrence was assessed in 150 consecutive survivors of cardiac arrest. Ventricular tachy-

cardia (≥6 beats) or ventricular fibrillation was induced in 113 patients (75%); ventricular arrhythmia was not induced in 37 patients (25%). During follow-up of a mean of 16 months (range 1 to 72), there were 65 arrhythmia recurrences (34 fatal) in 58 patients. Multivariate regression analysis showed that inducibility at initial study of ventricular tachycardia or ventricular fibrillation was an independent predictor of total arrhythmia recurrence ($p < 0.0001$) and fatal arrhythmia recurrence ($p = 0.02$). At 1 year, 25 ± 5% of patients with an inducible arrhythmia had a fatal arrhythmia recurrence compared with only 4 ± 4% of patients without ($p = 0.003$). Inducibility or noninducibility of ventricular arrhythmias at initial electrophysiologic study is a powerful, independent predictor of subsequent arrhythmia recurrence in survivors of cardiac arrest.

VALVULAR HEART DISEASE

583 Dual Balloon Technique for Valvuloplasty of Aortic Stenosis in Adults

Jeffrey M. Isner, Deeb N. Salem, Mark R. Desnoyers, Constance D. Fields, Kimberly R. Halaburka, Geralyn A. Slovenkai, Thomas J. Hougen, Eric J. Eichhorn, and Kenneth Rosenfield

Because results obtained using the single balloon technique for aortic balloon valvuloplasty may occasionally be suboptimal, we used a dual balloon technique in a series of 16 patients in whom the results of the single balloon technique were judged to be suboptimal. Use of the dual balloon technique accomplished a further decrease in peak aortic valve gradient and further increase in calculated aortic valve area that were statistically significant when compared with the results obtained with the single balloon alone. No complications were observed that were directly attributable to the dual balloon technique. These preliminary results suggest that dual balloon valvuloplasty is efficacious and safe in selected patients with aortic stenosis.

590 Effect of Mitral Regurgitation on Diastolic Filling with Left Ventricular Hypertrophy

M. Abubakr Shaikh and Steven J. Lavine

Mitral regurgitation has been demonstrated to increase early left ventricular diastolic filling. The effect of mitral regurgitation on early diastolic filling in patients with abnormal diastolic function is not clearly understood. Using transmitral pulsed Doppler recordings, we studied 32 normal patients, 21 patients with left ventricular hypertrophy, 23 with left ventricular hypertrophy with mitral regurgitation and 15 with mitral regurgitation. Mitral regurgitation patients demonstrated increased early and late filling velocities. Patients with hypertrophy demonstrated reduced early filling velocities, increased late filling velocities and a redistribution of diastolic filling to atrial systole. Patients with hypertrophy and mitral regurgitation demonstrated increased early filling velocities, increased late filling velocities and a normal distribution of diastolic filling. The presence of mitral regurgitation normalizes early diastolic filling in patients with left ventricular hypertrophy. Caution should be exercised when using diastolic filling to evaluate diastolic function in patients with mitral regurgitation.

BERLEX

QUINAGLUTE® (quinidine gluconate) DURA-TABS®

INDICATIONS AND USAGE: QUINAGLUTE® (quinidine gluconate) DURA-TABS® sustained-release tablets are indicated in the prevention and/or treatment of:

1. Ventricular arrhythmias: Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock). **2. Junctional (nodal) arrhythmias:** A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia, atrial flutter, atrial fibrillation (chronic and paroxysmal).

CONTRAINDICATIONS: 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.

WARNINGS: 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administation of quinidine.

2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered.

3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring.

4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals.

5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication.

6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity.

7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal.

8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4 to 8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.

PRECAUTIONS: General: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk.

Information for Patients: As with all solid oral medications, QUINAGLUTE® DURA-TABS® tablets should be taken with an adequate amount of fluid, preferably in an upright position, to facilitate swallowing.

Drug Interactions: *Drug*	*Effect*
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Potential for reduction of quinidine plasma levels
Quinidine with cimetidine	Potential for elevation of quinidine plasma levels
Quinidine with digoxin	Increased plasma concentrations of digoxin (see WARNINGS)

Carcinogenesis, Mutagenesis and Impairment of Fertility: Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.

Pregnancy: *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. QUINAGLUTE® DURA-TABS® tablets should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.

Nursing Mothers: Caution should be exercised when QUINAGLUTE® DURA-TABS® tablets are administered to a nursing woman due to passage of the drug into breast milk.

Pediatric Use: There are no adequate and well-controlled studies establishing the safety and effectiveness of QUINAGLUTE® DURA-TABS® tablets in children.

ADVERSE REACTIONS: Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea.

Less frequently encountered adverse reactions:

Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.

Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.

Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.

Dermatologic: Rash, cutaneous flushing with intense pruritis, urticaria. Photosensitivity has also been reported.

Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity, including granulomatous hepatitis (see WARNINGS). Although rare, there have been reports of lupus erythematosus in patients taking quinidine.

101-253 April 1987

EXPANDING TEXAS MULTISPECIALTY GROUP

Dallas/Ft. Worth Area, requires additional BE/BC cardiologists. Competitive salary. Extensive benefits. Direct inquiry and CV to: Medical Director, Permanente Medical Association of Texas, 12720 Hillcrest, Suite 600, Dallas, TX 75230.

CARDIOLOGIST—BC/BE to join busy cardiology practice in Los Angeles/Orange County area. University affiliation, excellent benefits and early partnership. Send CV to Box 805, The American Journal of Cardiology, 249 W. 17th St., New York, N.Y. 10011.

CARDIOLOGIST, BC/BE—Invasive and non-invasive cardiologist to join large and growing multispecialty group practice with active cardiology and cardiac surgery programs. Training in electrophysiology also desirable. Competitive salary, benefits and partnership offered. Send CV to: Ms. Martha Riddell, Director of Marketing, Lexington Clinic, 1221 South Broadway, Lexington, Kentucky 40504.

CARDIOLOGIST—36 physician multi-specialty group in college community of Beloit, Wisconsin seeks additional BC/BE cardiologist for invasive and non-invasive practice. Guaranteed salary with incentive plus excellent fringe benefits. Please submit letter with C.V. to: James F. Ruethling, Administrator, Beloit Clinic, S.C., 1905 Huebbe Parkway, Beloit, WI 53511.

INVASIVE/NON-INVASIVE CARDIOLOGY GROUP—Seeks BE/BC non-invasive cardiologist for thriving practice in growing Central Valley California community. Nine-man group affiliated with 3-hospital system offering wide range of cardiovascular services to large referral area. Competitive salary with future partnership. Reply Box 775, The American Journal of Cardiology, 249 W. 17th St., New York, N.Y. 10011.

CARDIOLOGIST

BC/BE cardiologist to be fifth member of consultative HMO practice in Denver. Needs to be adept at all current non-invasive techniques as well as left heart catheterization, coronary angiography and intra-aortic balloon placement. PTCA and permanent pacemaker experience not essential. For additional information, please contact:

V. A. LaFleur, M.D.
Associate Medical Director
Colorado Permanente Medical Group, P.C.
2045 Franklin Street
Denver, CO 80205
(303) 861-3262

EOE.

24-hour security for the hypertensive heart

First-step cardiovascular protection

Reduces workload of the heart by reducing myocardial O_2 demand

Preserves K^+ balance

Normalizes stress-induced systolic peaks with cardioselective beta-one blockade

Contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure.

Please consult Brief Summary of Prescribing Information on the following page.

Once-a-day in hypertension...

Lopressor®
metoprolol tartrate

Changing the Course of Cardiovascular Care

Geigy

First-step protection for the hypertensive heart

Lopressor®
metoprolol tartrate USP

Tablets
Ampuls
Prefilled Syringes

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

CONTRAINDICATIONS
Hypertension and Angina
Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **WARNINGS**).
Myocardial Infarction
Lopressor is contraindicated in patients with a heart rate < 45 beats/min; second- and third-degree heart block; significant first-degree heart block (P-R interval ≥ 0.24 sec); systolic blood pressure < 100 mmHg; or moderate-to-severe cardiac failure (see **WARNINGS**).

WARNINGS
Hypertension and Angina
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive and angina patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and Lopressor slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic. The response should be observed closely. If cardiac failure continues, despite adequate digitalization and diuretic therapy, Lopressor should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have occurred. When discontinuing chronically administered Lopressor, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of 1-2 weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Lopressor administration should be reinstated promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Lopressor therapy abruptly even in patients treated only for hypertension.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative $beta_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since $beta_1$ selectivity is not absolute, a $beta_2$-stimulating agent should be administered concomitantly, and the lowest possible dose of Lopressor should be used. In these circumstances it would be prudent initially to administer Lopressor in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See DOSAGE AND ADMINISTRATION.)**

Major Surgery: The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial; the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Lopressor, like other beta blockers, is a competitive inhibitor of beta-receptor agonists, and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes and Hypoglycemia: Lopressor should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade, which might precipitate a thyroid storm.

Myocardial Infarction
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function, and beta blockade carries the potential hazard of depressing myocardial contractility and precipitating or exacerbating minimal cardiac failure.

During treatment with Lopressor, the hemodynamic status of the patient should be carefully monitored. If heart failure occurs or persists despite appropriate treatment, Lopressor should be discontinued.

Bradycardia: Lopressor produces a decrease in sinus heart rate in most patients; this decrease is greatest among patients with high initial heart rates and least among patients with low initial heart rates. Acute myocardial infarction (particularly inferior infarction) may in itself produce significant lowering of the sinus rate. If the sinus rate decreases to < 40 beats/min, particularly if associated with evidence of lowered cardiac output, atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, Lopressor should be discontinued, and cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

AV Block: Lopressor slows AV conduction and may produce significant first- (P-R interval ≥0.26 sec), second-, or third-degree heart block. Acute myocardial infarction also produces heart block.

If heart block occurs, Lopressor should be discontinued and atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

Hypotension: If hypotension (systolic blood pressure ≤ 90 mmHg) occurs, Lopressor should be discontinued, and the hemodynamic status of the patient and the extent of myocardial damage carefully assessed. Invasive monitoring of central venous, pulmonary capillary wedge, and arterial pressures may be required. Appropriate therapy with fluids, positive inotropic agents, balloon counterpulsation, or other treatment modalities should be instituted. If hypotension is associated with sinus bradycardia or AV block, treatment should be directed at reversing these (see above).

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative $beta_1$ selectivity, Lopressor may be used with extreme caution in patients with bronchospastic disease. Because it is unknown to what extent $beta_2$-stimulating agents may exacerbate myocardial ischemia and the extent of infarction, these agents should *not* be used prophylactically. If bronchospasm not related to congestive heart failure occurs, Lopressor should be discontinued. A theophylline derivative or a $beta_2$ agonist may be administered cautiously, depending on the clinical condition of the patient. Both theophylline derivatives and $beta_2$ agonists may produce serious cardiac arrhythmias.**

PRECAUTIONS
General
Lopressor should be used with caution in patients with impaired hepatic function.
Information for Patients
Patients should be advised to take Lopressor regularly and continuously, as directed, with or immediately following meals. If a dose should be missed, the patient should take only the next scheduled dose (without doubling it). Patients should not discontinue Lopressor without consulting the physician.

Patients should be advised (1) to avoid operating automobiles and machinery or engaging in other tasks requiring alertness until the patient's response to therapy with Lopressor has been determined; (2) to contact the physician if any difficulty in breathing occurs; (3) to inform the physician or dentist before any type of surgery that he or she is taking Lopressor.
Laboratory Tests
Clinical laboratory findings may include elevated levels of serum transaminase, alkaline phosphatase, and lactate dehydrogenase.
Drug Interactions
Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension or marked bradycardia, which may produce vertigo, syncope, or postural hypotension.
Carcinogenesis, Mutagenesis, Impairment of Fertility
Long-term studies in animals have been conducted to evaluate carcinogenic potential. In 2-year studies in rats at three oral dosage levels of up to 800 mg/kg per day, there was no increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes that appeared to be drug related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in Swiss albino mice at three oral dosage levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant or total (benign plus malignant) lung tumors, nor in the overall incidence of tumors or malignant tumors. This 21-month study was repeated in CD-1 mice, and no statistically or biologically significant differences were observed between treated and control mice of either sex for any type of tumor.

All mutagenicity tests performed (a dominant lethal study in mice, chromosome studies in somatic cells, a Salmonella/mammalian-microsome mutagenicity test, and a nucleus anomaly test in somatic interphase nuclei) were negative.

No evidence of impaired fertility due to Lopressor was observed in a study performed in rats at doses up to 55.5 times the maximum daily human dose of 450 mg.
Pregnancy Category C
Lopressor has been shown to increase postimplantation loss and decrease neonatal survival in rats at doses up to 55.5 times the maximum daily human dose of 450 mg. Distribution studies in mice confirm exposure of the fetus when Lopressor is administered to the pregnant animal. These studies have revealed no evidence of impaired fertility or teratogenicity. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers
Lopressor is excreted in breast milk in very small quantity. An infant consuming 1 liter of breast milk daily would receive a dose of less than 1 mg of the drug. Caution should be exercised when Lopressor is administered to a nursing woman.
Pediatric Use
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
Hypertension and Angina
Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression has been reported in about 5 of 100 patients. Mental confusion and short-term memory loss have been reported. Headache, nightmares, and insomnia have also been reported.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations; congestive heart failure; peripheral edema; and hypotension have been reported in about 1 of 100 patients. (See **CONTRAINDICATIONS, WARNINGS,** and **PRECAUTIONS**.)

Respiratory: Wheezing (bronchospasm) and dyspnea have been reported in about 1 of 100 patients (see **WARNINGS**).

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, dry mouth, gastric pain, constipation, flatulence, and heartburn have been reported in about 1 of 100 patients.

Hypersensitive Reactions: Pruritus or rash have occurred in about 5 of 100 patients. Worsening of psoriasis has also been reported.

Miscellaneous: Peyronie's disease has been reported in fewer than 1 of 100,000 patients. Musculoskeletal pain, blurred vision, and tinnitus have also been reported.

There have been rare reports of reversible alopecia, agranulocytosis, and dry eyes. Discontinuation of the drug should be considered if any such reaction is not otherwise explicable.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor.
Myocardial Infarction
Central Nervous System: Tiredness has been reported in about 1 of 100 patients. Vertigo, sleep disturbances, hallucinations, headache, dizziness, visual disturbances, confusion, and reduced libido have also been reported, but a drug relationship is not clear.

Cardiovascular: In the randomized comparison of Lopressor and placebo described in the **CLINICAL PHARMACOLOGY** section, the following adverse reactions were reported:

	Lopressor	*Placebo*
Hypotension (systolic BP < 90 mmHg)	27.4%	23.2%
Bradycardia (heart rate < 40 beats/min)	15.9%	6.7%
Second- or third-degree heart block	4.7%	4.7%
First-degree heart block (P-R ≥ 0.26 sec)	5.3%	1.9%
Heart failure	27.5%	29.6%

Respiratory: Dyspnea of pulmonary origin has been reported in fewer than 1 of 100 patients.

Gastrointestinal: Nausea and abdominal pain have been reported in fewer than 1 of 100 patients.

Dermatologic: Rash and worsened psoriasis have been reported, but a drug relationship is not clear.

Miscellaneous: Unstable diabetes and claudication have been reported, but a drug relationship is not clear.
Potential Adverse Reactions
A variety of adverse reactions not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse reactions to Lopressor.

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **CONTRAINDICATIONS**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Hypersensitive Reactions: Fever combined with aching and sore throat, laryngospasm, and respiratory distress.

OVERDOSAGE
Acute Toxicity
Several cases of overdosage have been reported, some leading to death.

Oral LD_{50}'s (mg/kg): mice, 1158-2460; rats, 3090-4670.
Signs and Symptoms
Potential signs and symptoms associated with overdosage with Lopressor are bradycardia, hypotension, bronchospasm, and cardiac failure.
Treatment
There is no specific antidote.

In general, patients with acute or recent myocardial infarction may be more hemodynamically unstable than other patients and should be treated accordingly (see **WARNINGS, Myocardial Infarction**).

On the basis of the pharmacologic actions of Lopressor, the following general measures should be employed:

Elimination of the Drug: Gastric lavage should be performed.

Bradycardia: Atropine should be administered. If there is no response to vagal blockade, isoproterenol should be administered cautiously.

Hypotension: A vasopressor should be administered, e.g., levarterenol or dopamine.

Bronchospasm: A $beta_2$-stimulating agent and/or a theophylline derivative should be administered.

Cardiac Failure: A digitalis glycoside and diuretic should be administered. In shock resulting from inadequate cardiac contractility, administration of dobutamine, isoproterenol, or glucagon may be considered.

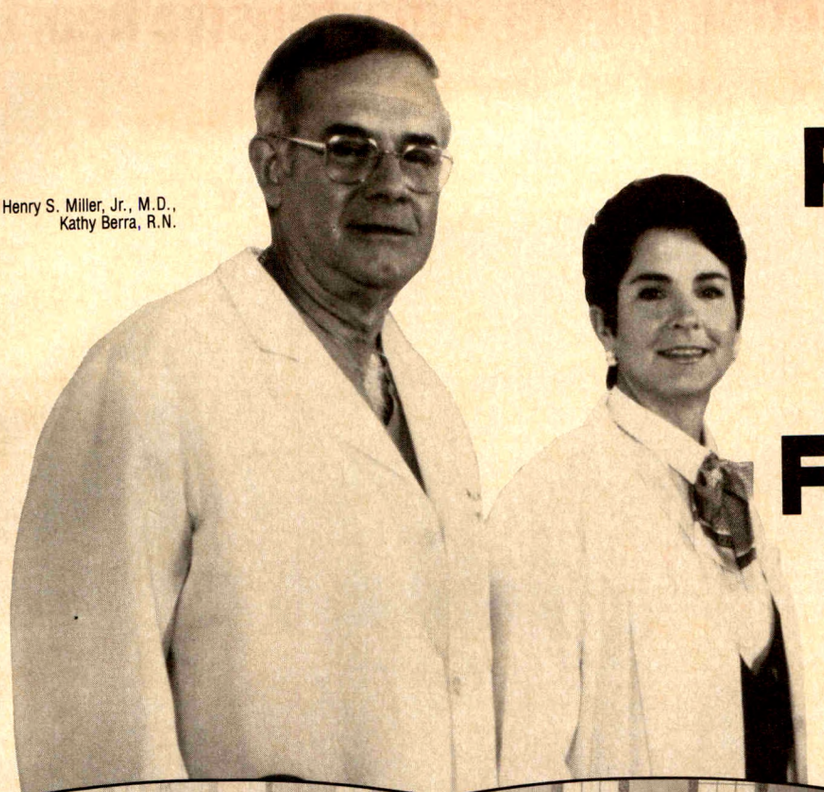
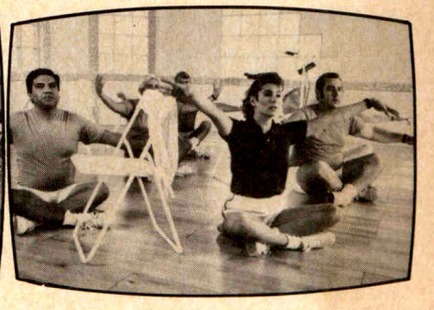
New Prescribed Video Programs For Cardiac Patients.

Special Offer For AJC Readers



Henry S. Miller, Jr., M.D.,
Kathy Berra, R.N.



Now available, the first take-home education and exercise video for cardiac patients. These four 60-minute videos extend rehabilitative care and meet the current standards of AHA and ACSM.

- Exercise videos feature increasing levels of intensity. Select the tape that's best for each patient. These video home programs encourage patient compliance.
- Patient exercise and activity log helps you audit progress during office visits.
- Available only on physician recommendation.

Prescription video orders can be filled at your office or rehab center for as low as $69-$89 each, depending on the module you prescribe.

VideoCare National Advisory Panel on Cardiac Rehabilitation

Physicians: Bruno Balke; Samuel M. Fox, III; Victor Froelicher, Peter Hanson; Herman K. Hellerstein; Terence Kavanagh; Arthur S.Leon; Henry S. Miller, Jr.; L. Kent Smith; C. Barr Taylor; Steven P. Van Camp.
Nurses: Kathy Berra; Nancy Houston Miller; Erika S. Sivarajan.
Exercise Physiologists: Carl Foster; Barry A. Franklin; William L. Haskell; Neil B. Oldridge; Michael L. Pollock; Paul M. Ribisl; Ray W. Squires.
Behavioral Scientist: James A. Blumenthal.
Physical Therapist: Elizabeth J. Protas.

Special AJC Offer

Normally $346, a complete VideoCare™ set can be obtained by AJC readers for only $300. Satisfaction guaranteed, credit cards accepted. **Call 1-800-338-1927.** Mention AJC for special offer.

VIDEOCARE, INC.

Yes! Please send four (4) VideoCare VHS cassettes, video brochure, and all support materials at special AJC price — only $300.00. Satisfaction guaranteed. (Foreign orders write for more information.)

IN CERTAIN DYSLIPIDEMIAS

A Desirable Balance of Efficacy

LOPID® *300 mg*
(gemfibrozil capsules, USP)

Lopid is indicated for treatment of adult patients with very high serum triglyceride levels in hyperlipoproteinemia other than type I who present a risk of pancreatitis and who do not respond adequately to diet.

© 1987 Warner-Lambert Company

with Patient Acceptance

Efficacy Lopid reduces synthesis[1-3] and increases clearance of triglyceride-rich VLDL.[2,3]

Patient acceptance Lopid has a very low order of side effects and has demonstrated limited effects on clinical and laboratory evaluations.[4]

Convenient BID dosage Two 300-mg capsules taken 30 minutes before morning and evening meals help ensure patient compliance.

Diet, exercise, and weight loss are the first choice in therapy of lipid disorders.

PARKE-DAVIS

Please see next page for references and a brief summary of prescribing information.

LOPID®
(gemfibrozil capsules, USP) 300 mg

Before prescribing, please see full prescribing information. A Brief Summary follows:

CLINICAL PHARMACOLOGY. LOPID is a lipid regulating agent which lowers elevated serum lipids primarily by decreasing serum triglyceride with a variable reduction in total serum cholesterol. These decreases occur primarily in the very low density lipoprotein (VLDL) fraction and less frequently in the low density lipoprotein (LDL) fraction. It has been reported that LOPID may increase levels of high density lipoprotein (HDL) subfractions, HDL_2 and HDL_3 as well as apolipoproteins AI and AII. Epidemiological studies have shown that both low HDL-cholesterol and high LDL-cholesterol are independent risk factors for coronary heart disease. It is not yet known whether pharmacological interventions designed to raise HDL-cholesterol alter morbidity or mortality due to coronary heart disease.

The mechanism of action has not been definitively established. In man, LOPID has been shown to inhibit peripheral lipolysis and to decrease the hepatic extraction of free fatty acids, thus reducing hepatic triglyceride production. LOPID inhibits synthesis and increases clearance of VLDL carrier apolipoprotein B, leading to a decrease in VLDL production.

Animal studies suggest that LOPID may, in addition to elevating HDL cholesterol, reduce incorporation of long-chain fatty acids into newly formed triglycerides, accelerate turnover and removal of cholesterol from the liver, and increase excretion of cholesterol in the feces.

LOPID is well absorbed from the gastrointestinal tract after oral administration. Peak plasma levels occur in one to two hours with a plasma half-life of 1.5 hours following multiple doses. Plasma levels appear proportional to dose and do not demonstrate accumulation across time following multiple doses.

LOPID mainly undergoes oxidation of a ring methyl group to successively form a hydroxymethyl and a carboxyl metabolite. Approximately seventy percent of the administered human dose is excreted in the urine, mostly as the glucuronide conjugate, with less than 2% excreted as unchanged gemfibrozil. Six percent of the dose is accounted for in the feces.

In a large, controlled multicenter trial of 427 patients, lipid and lipoprotein changes from average baseline (%) by hyperlipoproteinemic (HLP) type are summarized below for those patients receiving gemfibrozil, 1200 mg/day, at the end of 12 weeks.

HLP Type	TRIGLYCERIDE	CHOLESTEROL				RATIO: HDL Cholesterol / Total Cholesterol
		Total	VLDL	LDL	HDL	
IIa	−44%	−4.2%	−44.3%	−5.8%	+24.6%	+33%
IIb	−45%	−8.6%	−45.0%	−6.4%	+19.5%	+34%
IV	−40%	−1.8%	−40.8%	+14.6%	+17.4%	+23%

INDICATIONS AND USAGE. The initial treatment for hyperlipidemia is dietary therapy specific for the type of hyperlipoproteinemia. Drug therapy should not be used for the routine treatment of elevated blood lipids for the prevention of coronary heart disease. Excess body weight and excess alcoholic intake may be important factors in hypertriglyceridemia and should be addressed prior to any drug therapy. Physical exercise can be an important ancillary measure. Contributory diseases such as hypothyroidism or diabetes mellitus should be looked for and adequately treated. The use of drugs should be considered only when reasonable attempts have been made to obtain satisfactory results with nondrug methods. If the decision is to use drugs, the patient should be instructed that this does not reduce the importance of adhering to diet.

Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, and the adverse findings with clofibrate in two large clinical studies (see Warnings), use of gemfibrozil should be restricted to the following indications.

LOPID may be considered for the treatment of adult patients with very high serum triglyceride levels (type IV or type V hyperlipoproteinemia) who present a risk of abdominal pain and pancreatitis and who do not respond adequately to a determined dietary effort to control them. Patients with triglyceride levels in excess of 750 mg per deciliter are likely to present such risk. LOPID has little effect on elevated cholesterol levels in most subjects. A minority of subjects show a more pronounced response. Therefore, the physician should be very selective and confine gemfibrozil treatment to patients with clearly defined risk due to severe hypercholesterolemia (eg, individuals with familial hypercholesterolemia starting in childhood) who inadequately respond to appropriate diet and more effective cholesterol-lowering drugs.

LOPID is not useful for the hypertriglyceridemia of Type I hyperlipidemia.

The biochemical response to gemfibrozil is variable, and it is not always possible to predict from the lipoprotein type or other factors which patients will obtain favorable results. It is essential that lipid levels be assessed and that the drug be discontinued after three months in any patient in whom lipids do not show significant improvement.

The effect of gemfibrozil-induced reduction of serum cholesterol or triglyceride levels or elevation of HDL cholesterol levels on morbidity or mortality due to coronary heart disease has not been established. Several years may be required before ongoing long-term investigations will resolve this question.

CONTRAINDICATIONS. 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease. (See Warnings).

3. Hypersensitivity to gemfibrozil.

WARNINGS. 1. Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization, 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant 36% higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to noncardiovascular causes, including malignancy, postcholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

2. Long-Term Toxicity and Animal Tumorigenicity Studies—Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant (p greater than 0.05). There were no statistically significant differences from controls in the incidence of liver tumors in female rats, and in male and female mice.

Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following LOPID (gemfibrozil capsules, USP) administration to the male rat. Similar changes have not been found in the human liver.

Male rats had a dose-related increase of benign Leydig cell tumors. Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of the high dose males.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and liver and interstitial cell testicular tumors were increased in male rats, LOPID should be administered only to those patients described in the Indications and Usage Section. If a significant serum lipid response is not obtained, LOPID should be discontinued.

4. Cholelithiasis—LOPID may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected gallbladder studies are indicated. LOPID therapy should be discontinued if gallstones are found.

5. Concomitant Anticoagulants—Caution should be exercised when anticoagulants are given in conjunction with LOPID. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

PRECAUTIONS. 1. **Initial Therapy**—Before instituting LOPID therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and other medical problems such as diabetes mellitus and hypothyroidism.

2. **Continued Therapy**—Pretreatment laboratory studies should be performed to ensure that patients have abnormal levels of serum lipids. Periodic determinations of serum lipids should be obtained during LOPID administration. The drug should be withdrawn after three months if the lipid response is inadequate.

3. **Impairment of Fertility**—Administration of approximately three and ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to their offspring.

4. **Pregnancy Category B**—Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 6.7 times the human dose. These studies have revealed no evidence of impaired fertility in females or harm to the fetus due to LOPID. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that LOPID is tumorigenic in male rats, the use of LOPID in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

5. **Nursing Mothers**—Because of the potential for tumorigenicity shown for gemfibrozil in male rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

6. **Hematologic Changes**—Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of LOPID therapy. However, these levels stabilize during long-term administration. Therefore, periodic blood counts are recommended during the first 12 months of LOPID administration.

7. **Liver Function**—Abnormal liver function tests have been observed occasionally during LOPID administration, including elevations of SGOT, SGPT, LDH, and alkaline phosphatase. These are usually reversible when LOPID is discontinued. Therefore periodic liver function studies are recommended and LOPID therapy should be terminated if abnormalities persist.

8. **Use in Children**—Safety and efficacy in children have not been established.

ADVERSE REACTIONS. In controlled clinical trials of 805 patients, including 245 who received LOPID for at least one year, the most frequently reported adverse reactions associated with LOPID involved the gastrointestinal system. In decreasing order of frequency, these were abdominal pain (6.0%), epigastric pain (4.9%), diarrhea (4.8%), nausea (4.0%), vomiting (1.6%), and flatulence (1.1%). Other adverse reactions where the probability of a causal relationship to LOPID therapy exists are listed by system.

Integumentary: rash, dermatitis, pruritus, urticaria

Central Nervous System: headache, dizziness, blurred vision

Musculoskeletal: painful extremities

Hematopoietic: anemia, eosinophilia, leukopenia

Other reactions have been reported under conditions where a causal relationship is difficult to establish, thus the physician should be alert to these occurrences. Reports of viral and bacterial infections (common cold, cough, and urinary tract infections) were more common in gemfibrozil than in placebo-treated patients.

Other reactions were:

Gastrointestinal: dry mouth, constipation, anorexia, gas pain, dyspepsia

Musculoskeletal: back pain, arthralgia, muscle cramps, myalgia, swollen joints, myositis

Central Nervous System: vertigo, insomnia, paresthesia, tinnitus

Clinical Laboratory: hypokalemia, liver function abnormalities (increased SGOT, SGPT, LDH, CPK, alkaline phosphatase)

Miscellaneous: fatigue, malaise, syncope, alopecia

DOSAGE AND ADMINISTRATION. The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meal. Some patients will experience therapeutic effects on 900 mg/day; a few may require 1500 mg/day for satisfactory results.

DRUG INTERACTIONS. CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID. THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

MANAGEMENT OF OVERDOSAGE. While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

Caution—Federal law prohibits dispensing without prescription.

595 Noninvasive Assessment of Hemodynamic Responses to Exercise in Pulmonary Regurgitation After Operations to Correct Pulmonary Outflow Obstruction

Gerald R. Marx, Richard W. Hicks, Hugh D. Allen, and Stanley J. Goldberg

The purpose of this study was to determine the hemodynamic responses to exercise in postoperative patients with pulmonary regurgitation (PR) using Doppler-measured regurgitant fraction to indicate severity of disease. Maximal heart rate, oxygen consumption and workload capacity were measured during upright cycle ergometry. Cardiac output was measured at rest and during submaximal supine cycle ergometry by pulsed Doppler echocardiography. Oxygen consumption was simultaneously measured and exercise factor was calculated as the change in cardiac output per change in oxygen consumption. Twenty-seven patients were compared with 17 age-, size- and sex-matched control subjects. PR patients had larger right ventricles ($p \leq 0.001$); lower heart rate response ($p \leq 0.05$), lower maximal oxygen consumption ($p \leq 0.005$) and lower workloads ($p \leq 0.005$) during maximal exercise testing. Exercise factor was the same for both groups. Patients with mild PR had a normal response to exercise. However, patients with moderate and severe PR had lower maximal oxygen consumptions and maximal workloads compared with control subjects. Control, mild and moderate PR groups had similar exercise factors. Patients with severe PR and markedly low cardiac output responses. PR is associated with reduced exercise capability, which is related to disease severity.

602 Results of the Modified Fontan Operation in Adults

Richard A. Humes, Douglas D. Mair, Co-Burn J. Porter, Francisco J. Puga, Hartzell V. Schaff, and Gordon K. Danielson

The results of the modified Fontan operation in 77 patients 18 years of age and older indicated that the procedure can be performed with low mortality. The long-term outcome is favorable, but persistent ascites and edema may be a problem in some patients.

605 Effect of Iron Deficiency on Tissue Oxygen Delivery in Cyanotic Congenital Heart Disease

Samuel S. Gidding and James A. Stockman III

To test the hypothesis that tissue oxygen delivery would be affected by diminished iron stores in cyanotic congenital heart disease, serum ferritin, transferrin saturation, hemoglobin, red cell mean corpuscular volume (MCV), diphosphoglycerate (DPG), P50, blood gases, oxygen saturations and systemic oxygen transport were measured in 29 hypoxemic infants and children. When patients with P50 $\geq$30 mm Hg and P50 $<$30 mm Hg were compared, serum ferritin, transferrin saturation and MCV were significantly diminished in the high P50 group. Hemoglobin, aortic oxy-

gen saturation, PaO_2 and systemic oxygen transport were similar in both groups. In children with iron sufficiency, 15 of 21 had MCV >90th percentile for age and sex. Also, MCV >90th percentile has a positive predictive value of 0.88 for iron sufficiency. Thus, diminished iron stores are associated with a more right-shifted oxyhemoglobin dissociation curve (increased P50), and MCV >90th percentile is a marker for iron sufficiency in hypoxemic patients.

608 Surgical Risk Factors in Total Anomalous Pulmonary Venous Connection

Christopher R. Lincoln, Michael L. Rigby, Corrado Mercanti, Mohammad Al-Fagih, Michael C. Joseph, Graham A. Miller, and Elliott A. Shinebourne

Eighty-three patients underwent surgical correction of total anomalous pulmonary venous connection from 1973 to 1986. Diagnosis was established by cardiac catheterization and angiography in 56 patients, by clinical examination in 3, and by cross-sectional echocardiography alone in 24 of the last consecutive 28 patients. Pulmonary hypertension was present in 55% of those who underwent cardiac catheterization. Ten patients developed 1 or more pulmonary hypertensive crises during the early postoperative period. Analysis of risk factors for 30-day survival for all patients showed that the risk of early death was associated with the type of anomaly (infradiaphragmatic), occurrence of pulmonary hypertensive crises, year of operation, sex of the patient, and presence of preoperative heart failure. The 30-day hospital mortality from 1975 to the present is 8.5%.

612 Accuracy of Electrical Impedance Cardiography for Measuring Cardiac Output in Children with Congenital Heart Defects

Daniel S. Miles, Robert W. Gotshall, Jane C. Golden, Dwight T. Tuuri, Robert H. Beekman III, and Terrence Dillon

The noninvasive technique of impedance cardiography was used to measure systemic blood flow (cardiac output) in children with congenital heart defects. Results were compared with values obtained for systemic blood flow measured by the direct Fick procedure. Patients evaluated consisted of a control group (n = 11) with no shunts, a group with intracardiac left-to-right shunting and an atrial septal defect (n = 7), another with a ventricular septal defect (n = 12), and an extracardiac left-to-right shunting with patent ductus arteriosus group (n = 7). The difference between systemic blood flow measured by the impedance or Fick techniques was ≤5% in each of the 4 groups. Impedance cardiography accurately measured systemic blood flow in children without shunts or valvular insufficiency. Likewise, systemic blood flow was accurately measured by impedance in the presence of intra- or extracardiac left-to-right shunting.

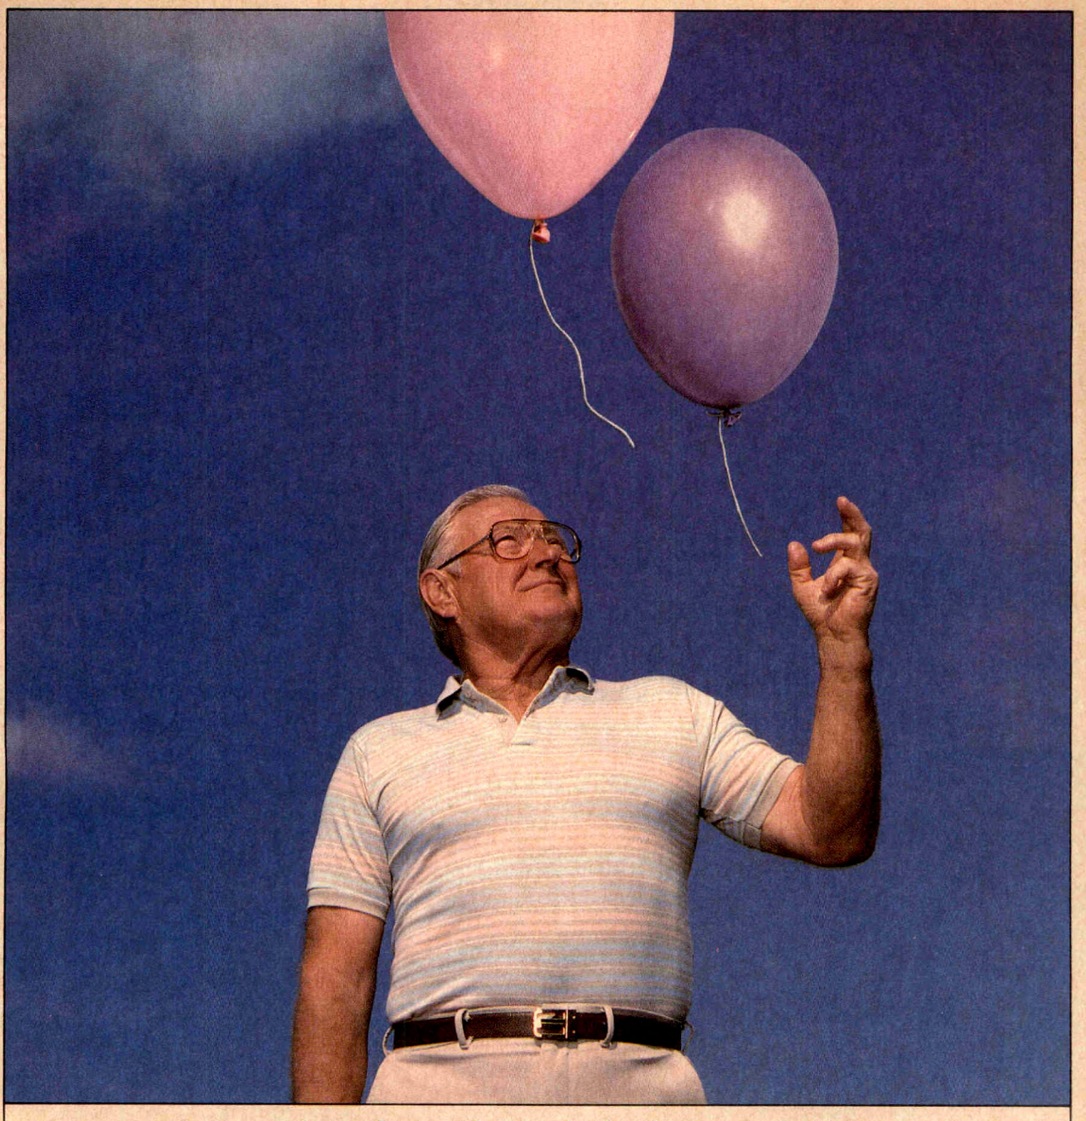
GENTLE RELEASE



Prescribe a slow and easy dual release mechanism when selecting a solid potassium supplement.

KLOTRIX® is the only slow-release KCl that employs a dual release mechanism: a wax matrix plus a patented permeable membrane coating.

for the patient who can't or won't drink liquid KCl

KLOTRIX®
(POTASSIUM CHLORIDE)

controlled-release tablets, 10 mEq

THE GENTLE ONE

© 1986 Mead Johnson & Company • Evansville, Indiana 47721 U.S.A. J-V5

(Please see Brief Summary of Prescribing Information on the following page)

KLOTRIX®
(POTASSIUM CHLORIDE)
CONTROLLED-RELEASE TABLETS, 10 mEq

DESCRIPTION: KLOTRIX is a film-coated (not enteric-coated) tablet containing 750 mg potassium chloride (equivalent to 10 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS: BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS: In patients with hyperkalemia, since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium. All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the GI tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS: Hyperkalemia: In patients with impaired mechanisms for excreting potassium, administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium intravenously but may also occur when given orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. Use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with potassium-sparing diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. KLOTRIX is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years), cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient-years. KLOTRIX should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS: Potassium depletion is ordinarily diagnosed by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Treatment of potassium depletion particularly in presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, electrocardiogram and clinical status of patient.

ADVERSE REACTIONS: Most common to oral potassium salts: nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose. One of the most severe adverse effects is hyperkalemia (see Contraindications and Warnings). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE AND ADMINISTRATION: The usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires the loss of 200 or more mEq of potassium from the total body store. Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for the prevention of hypokalemia to 40-100 mEq per day or more for the treatment of potassium depletion.

Note: KLOTRIX® slow-release tablets must be swallowed whole and never crushed or chewed. Following release of the potassium chloride, the expended wax matrix, which is not absorbed, may be observed in the stool.

HOW SUPPLIED: Bottles of 100, 1000, and Unit Dose cartons of 100.

CARDIOLOGIST—BC/BE sought to join a large hospital-based multi-specialty clinic. University affiliated residency program. Excellent fringe benefits. Competitive salary. California license required. Send CV to Aung-Win Chiong, MD, THE PERMANENTE MEDICAL GROUP, INC., P.O. Box 254999, Sacramento, CA 95865-4999, or call (916) 973-5748. An equal opportunity employer.

CARDIOLOGIST—A large Cardiology Practice in a major Northeastern City is seeking a well qualified Cardiologist to join an established growing Referral Practice. The Practice offers well rounded clinical, invasive and non-invasive opportunities, affiliation with a major Medical Center, and a large private Teaching Hospital. Please send letter and curriculum vitae to Box 695, The American Journal of Cardiology, 249 W. 17th St., New York, N.Y. 10011.

Cardiologist

LOVELACE

MEDICAL CENTER

Lovelace Medical Center, a 230-bed hospital located in Albuquerque, New Mexico, is seeking a **Cardiologist** to join a group of 4 Cardiologists. Our institution provides a full range of cardiovascular health care including an active cardiac catheterization lab which is involved in diagnostic catheterization as well as urgent and elective coronary angioplasty, valvuloplasty, and electrophysiologic studies. We also have an active cardiac surgery program and have a strong affiliation with the University of New Mexico training program for cardiology fellows.

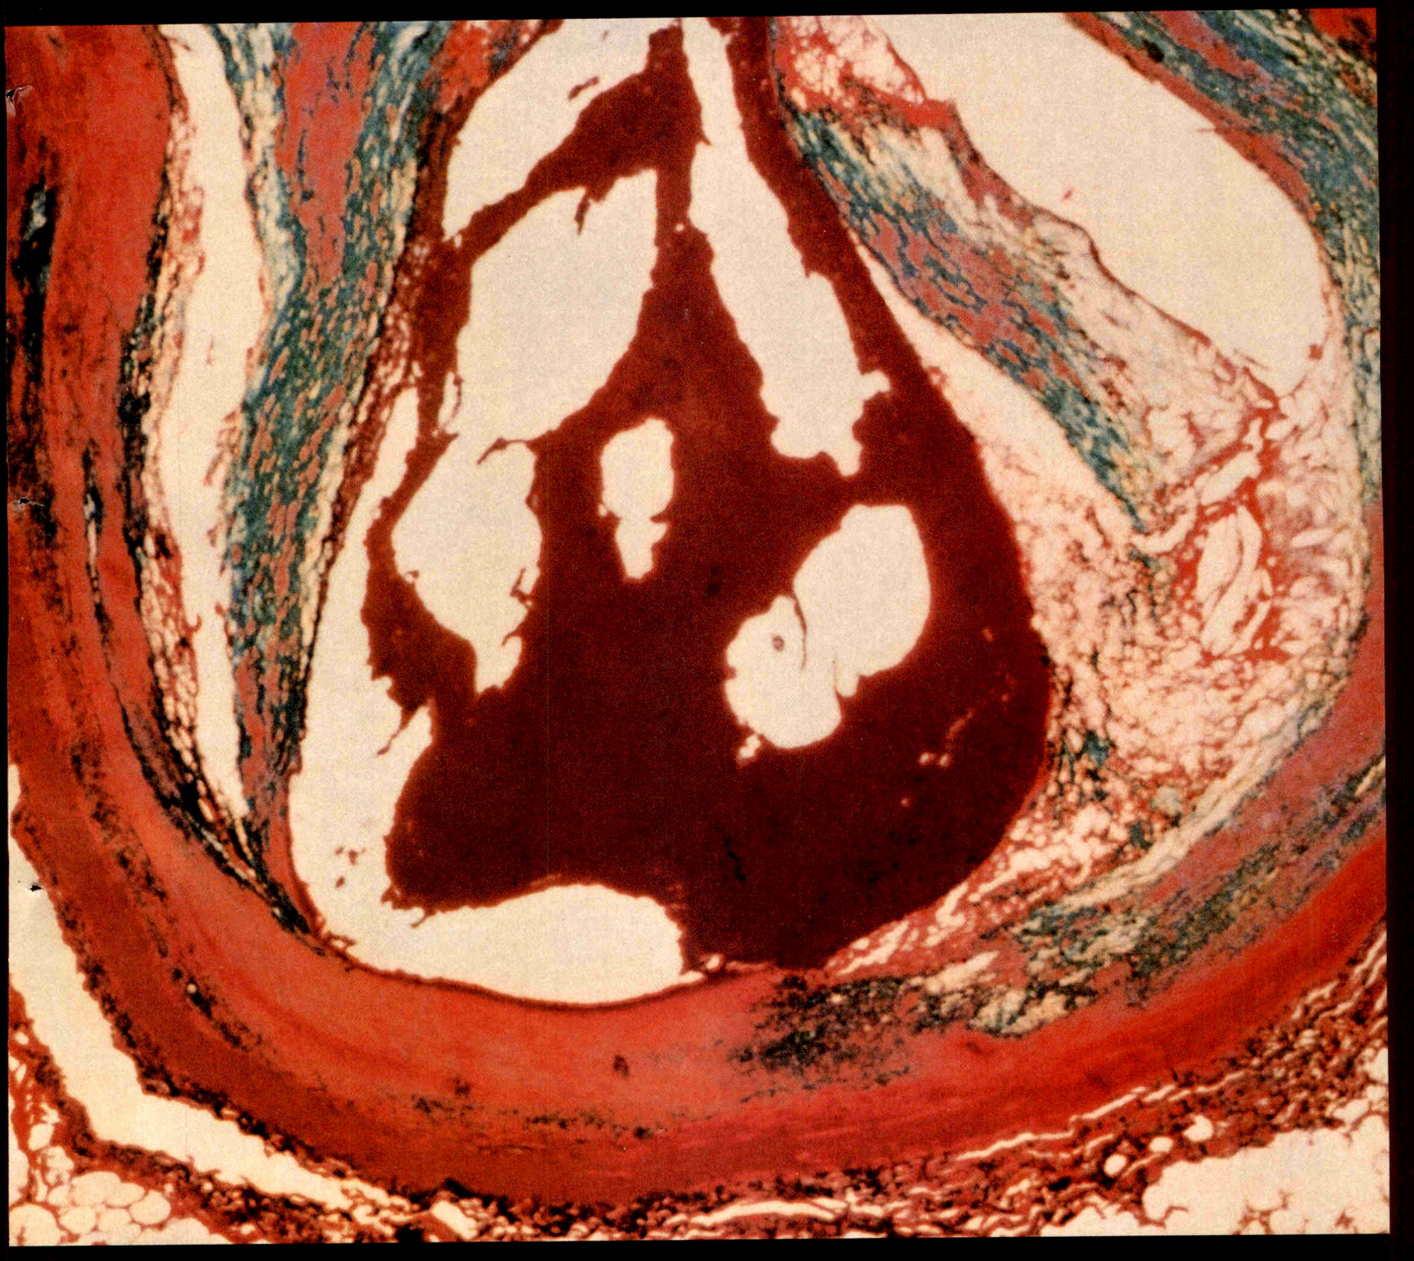
Lovelace Medical Center has opened a new hospital with an 8-bed Coronary Care Unit, a 2-bed open-heart recovery with an additional 10-bed Intensive Care Unit. State-of-the-art telemetry capabilities for arrhythmias detection are available in a step-down unit. The Cardiology Division also offers state-of-the-art echo and Doppler evaluations and the full range of cardiac nuclear studies.

The candidate we seek should be a fully trained cardiologist, specializing in noninvasive cardiology who is ABIM certified and board eligible or board certified in cardiology. Responsibilities will include supervising the noninvasive laboratory as well as the full range of clinical cardiovascular care and the education and training of Fellow within the Cardiology Department at the University of New Mexico. Attractive salary and benefits package is available. Please submit your curriculum vitae and letters of professional reference to: **Robert P. Croke, M.D. FACC, Chairman, Department of Cardiology, Lovelace Medical Center, 5400 Gibson Blvd SE, Albuquerque, NM 87108.**

Equal Opportunity Employer M/F/V/H

In the first critical hour of acute MI

MORTALITY REDUCED UP TO 47%



Cross section of a cardiac artery showing atheromatous plaque and occluding thrombus.

...and ventricular function improved.

Artist's interpretation of thrombolysis of a coronary artery occlusion.

Now...for acute MI

Intravenous

Streptase®

(Streptokinase)

Mortality reduced, ventricular function improved, unique benefits beyond lysis.

Lower in-hospital mortality with an acceptable level of risk[1]

- Multicenter trial with almost 12,000 randomized acute MI patients reported in *The Lancet*
- 1.5 million units of streptokinase plus conventional therapy vs. conventional therapy alone
- 47% less mortality with IV streptokinase given within one hour of onset of chest pain
- 23% less mortality with IV streptokinase given within three hours
- 17% less mortality with IV streptokinase given within six hours
- Incidence of major and minor complications considered acceptable

Improved cardiac function with few adverse effects[2]

- Randomized, placebo-controlled trial with 172 first-infarction patients, reported in *New England Journal of Medicine*, Oct 1, 1987
- 1.5 million units of streptokinase plus conventional therapy (including anticoagulants) vs. placebo infusion plus conventional therapy within four hours of onset of chest pain
- Coronary artery reperfusion shown by earlier peak of myocardial creatine kinase
- Significant increase in left ventricular ejection fraction and significant reduction in end-systolic volume confirmed by left ventricular angiography
- In this study, the most serious adverse effect was manageable hypotension

Benefits beyond thrombolysis

- Decreases red blood cell aggregation, and plasma and blood viscosity[3-5]
- Reduces blood pressure and total peripheral resistance with corresponding reduction in cardiac afterload for reduced myocardial oxygen demand[6-8]

Timing, dosage, and patient selection criteria

- Earliest treatment gives the best results
- Dosage: 1.5 million international units of streptokinase; duration of infusion up to 60 minutes
- Risk vs. benefits must be considered.

—Contraindications include active internal bleeding; recent (within two months) cerebral vascular accident, intracranial or intraspinal injury; intracranial neoplasm; and severe, uncontrolled hypertension

—*Risk of bleeding:* From pooled data of studies of 8,369 patients, the overall incidence of major bleeding was 1.2%. Nonetheless, physicians should be alert to untoward bleeding events. (Consult Warnings section of Streptase full prescribing information.)

Please see references and brief summary of prescribing information at end of this advertisement.

Intravenous

Streptase®

In the critical hours of acute MI

For acute MI
Intravenous

Streptase®
(Streptokinase)

The only thrombolytic that provides all these important benefits:

Proof of increased survival
- Reduction in mortality documented in a randomized study with almost 12,000 patients[1]

Proof of improved cardiac function
- Angiographic confirmation of improved left ventricular function[2]

Unique actions for greater reductions in cardiac stress
- Extrathrombolytic activity—reduces blood pressure, red blood cell aggregation, and blood and plasma viscosity[3-8]

Speed and simplicity in a one-step regimen
- Convenient, 1-hour constant-rate infusion compared to a 3 hour variable rate infusion with tissue plasminogen activator (r-TPA)

Staff confidence through many years of experience
- 10 years' experience in U.S. hospitals—and 25 years' worldwide—in lytic therapy

A tradition of service and support
- Extensive inservice training, important speakers' programs, and personal service by 650 skilled representatives to meet your hospital's needs

...all this at 90% less cost
- Priced at less than 10% of the reported cost of tissue plasminogen activator (r-TPA)

Bleeding, allergy and fever are the most frequent side effects seen with streptokinase; during treatment of myocardial infarction, hypotension and arrhythmias have been reported. Please see Warnings section of prescribing information before using Streptase®.

STREPTASE®
(Streptokinase)

Brief Summary
Consult full prescribing information before using.

INDICATIONS AND USAGE
Acute Evolving Transmural Myocardial Infarction
Streptase®, Streptokinase, is indicated for use in the management of acute myocardial infarction in adults, for the lysis of intracoronary thrombi, for the improvement of ventricular function, and reduction of mortality when administered by either the intravenous or intracoronary route. Earlier administration of Streptokinase is correlated with greater clinical benefit. See CLINICAL PHARMACOLOGY section of full prescribing information.

CONTRAINDICATIONS
Because thrombolytic therapy increases the risk of bleeding, Streptase®, Streptokinase, is contraindicated in the following situations:
- —Active internal bleeding
- —Recent (within 2 months) cerebrovascular accident, intracranial or intraspinal surgery (see WARNINGS)
- —Intracranial neoplasm
- —Severe uncontrolled hypertension.

Streptokinase should not be administered to patients having experienced severe allergic reaction to the product.

WARNINGS
Bleeding
Streptase®, Streptokinase, will cause lysis of hemostatic fibrin deposits such as those occurring at sites of needle punctures, and bleeding may occur from such sites. In order to minimize the risk of bleeding during treatment with Streptokinase, venipunctures and physical handling of the patient should be performed carefully and as infrequently as possible, and intramuscular injections must be avoided.
Should arterial puncture be necessary during intravenous therapy, upper extremity vessels are preferable. Pressure should be applied for at least 30 minutes, a pressure dressing applied, and the puncture site checked frequently for evidence of bleeding.
In the following conditions the risks of therapy may be increased and should be weighed against the anticipated benefits.
- —Recent (within 10 days) major surgery, obstetrical delivery, organ biopsy, previous puncture of noncompressible vessels
- —Recent (within 10 days) serious gastrointestinal bleeding
- —Recent (within 10 days) trauma including cardiopulmonary resuscitation
- —Hypertension: systolic BP ≥ 180 mm Hg and/or diastolic BP ≥ 110 mm Hg
- —High likelihood of left heart thrombus, e.g., mitral stenosis with atrial fibrillation
- —Subacute bacterial endocarditis
- —Hemostatic defects including those secondary to severe hepatic or renal disease
- —Pregnancy
- —Cerebrovascular disease
- —Diabetic hemorrhagic retinopathy
- —Septic thrombophlebitis or occluded AV cannula at seriously infected site
- —Any other condition in which bleeding constitutes a significant hazard or would be particularly difficult to manage because of its location.

Should serious spontaneous bleeding (not controllable by local pressure) occur, the infusion of Streptase®, Streptokinase, should be terminated immediately and treatment instituted as described under ADVERSE REACTIONS.

Arrhythmias
Rapid lysis of coronary thrombi has been shown to cause reperfusion atrial or ventricular dysrhythmias requiring immediate treatment. Careful monitoring for arrhythmia is recommended during and immediately following administration of Streptase®, Streptokinase, for acute myocardial infarction.

Hypotension
Hypotension, sometimes severe, not secondary to bleeding or anaphylaxis has been observed during intravenous Streptase®, Streptokinase, infusion in 1% to 10% of patients. Patients should be monitored closely and, should symptomatic or alarming hypotension occur, appropriate treatment should be administered. This treatment may include a decrease in the intravenous Streptokinase infusion rate. Smaller hypotensive effects are common and have not required treatment.

Other
Non-cardiogenic pulmonary edema has been reported rarely in patients treated with Streptase®, Streptokinase. The risk of this appears greatest in patients who have large myocardial infarctions and are undergoing thrombolytic therapy by the intracoronary route.
Rarely, polyneuropathy has been temporally related to the use of Streptase®, Streptokinase.
Should pulmonary embolism or recurrent pulmonary embolism occur during Streptase®, Streptokinase, therapy, the originally planned course of treatment should be completed in an attempt to lyse the embolus. While pulmonary embolism may occasionally occur during Streptokinase treatment, the incidence is no greater than when patients are treated with heparin alone.

PRECAUTIONS
General
Because of the increased likelihood of resistance, due to antistreptokinase antibody, Streptase®, Streptokinase, may not be effective if administered between five days and six months of prior Streptokinase administration or streptococcal infections, such as streptococcal pharyngitis, acute rheumatic fever, or acute glomerulonephritis secondary to a streptococcal infection.

Laboratory Tests
Intravenous or Intracoronary Infusion for Myocardial Infarction
Intravenous administration of Streptase®, Streptokinase, will cause marked decreases in plasminogen and fibrinogen and increases in thrombin time (TT), activated partial thromboplastin time (APTT), and prothrombin time (PT). These changes may also occur in some patients with intracoronary administration of Streptokinase.
Intravenous Infusion for Other Indications. Before commencing thrombolytic therapy, it is desirable to obtain an activated partial thromboplastin time (APTT), a prothrombin time (PT), a thrombin time (TT), fibrinogen levels, and a hematocrit and platelet count. If heparin has been given, it should be discontinued and the TT or APTT should be less than twice the normal control value before thrombolytic therapy is started.
During the infusion, decreases in plasminogen and fibrinogen levels and an increase in the level of FDP (the latter two causing a prolongation in the clotting times of coagulation tests) will generally confirm the existence of a lytic state. Therefore, lytic therapy can be confirmed by performing the TT, APTT, PT, or fibrinogen levels approximately 4 hours after initiation of therapy. If heparin is to be (re)instituted following the Streptase®, Streptokinase, infusion, the TT or APTT should be less than twice the normal control value (see manufacturer's prescribing information for proper use of heparin).

Drug Interactions
The interaction of Streptase®, Streptokinase, with other drugs has not been well studied.
Use of Anticoagulants and Antiplatelet Agents. Streptase®, Streptokinase, alone or in combination with antiplatelet agents and anticoagulants, may cause bleeding complications. Therefore, careful monitoring is advised. Concurrent use of antiplatelet agents such as aspirin, dipyridamole, or nonsteroidal antiinflammatory agents is not recommended.
Anticoagulation After Treatment for Myocardial Infarction. The administration of anticoagulant and/or antiplatelet drugs following administration of Streptase®, Streptokinase, appears to increase the risk of bleeding (see ADVERSE REACTIONS). These agents have been used in an attempt to prevent reocclusion of the target vessel. Use of anticoagulants or antiplatelet drugs following administration of Streptokinase has not yet been shown to be of unequivocal clinical benefit. Therefore, the use of anticoagulant and/or antiplatelet regimens should be individualized.
Anticoagulation after IV Treatment for Other Indications. Continuous intravenous infusion of heparin, without a loading dose, has been recommended following termination of Streptase®, Streptokinase, infusion for treatment of pulmonary embolism or deep vein thrombosis to prevent rethrombosis. The effect of Streptokinase on thrombin time (TT) and activated partial thromboplastin time (APTT) will usually diminish within 3 to 4 hours after Streptokinase therapy, and heparin therapy without a loading dose can be initiated when the TT or the APTT is less than twice the normal control value.

Pregnancy
Pregnancy Category C. Animal reproduction studies have not been conducted with Streptase®, Streptokinase. It is also not known whether Streptokinase can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Streptokinase should be given to a pregnant woman only if clearly needed.

Pediatric Use
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
The following adverse reactions have been associated with intravenous therapy and may also occur with intracoronary artery infusion:

Bleeding
The incidence of bleeding (major or minor) varied widely from study to study depending on dosage, patient population and concomitant therapy.
Minor bleeding can be anticipated mainly at invaded or disturbed sites. If such bleeding occurs, local measures should be taken to control the bleeding.
Severe internal bleeding involving gastrointestinal, genitourinary, retroperitoneal, or intracerebral sites has occurred and has resulted in fatalities. In three studies in which anticoagulation was optional following intravenous administration of Streptase®, Streptokinase, for acute myocardial infarction, the incidence of major bleeding ranged from 0.3%-6.2%. In 21 studies in which anticoagulation was compulsory, the incidence of major bleeding ranged from 0-16%. The overall incidence of major bleeding with intravenous infusion is 1%-2%.
Major bleed rates are difficult to determine for other dosages and patient populations because of the different dosing and intervals of infusions. The rates reported appear to be within the ranges reported for intravenous administration in acute myocardial infarction.
Should uncontrollable bleeding occur, Streptokinase infusion should be terminated immediately. Slowing the rate of administration of Streptokinase will not help correct bleeding and may make it worse. If necessary, bleeding can be reversed and blood loss effectively managed with appropriate replacement therapy. Although the use of aminocaproic acid (ACA, AMICAR®) in humans as an antidote for Streptokinase has not been documented, it may be considered in an emergency situation.

Allergic Reactions
Anaphylactic and anaphylactoid reactions have been observed rarely in patients treated intravenously with Streptase®, Streptokinase. These ranged in severity from minor breathing difficulty to bronchospasm, periorbital swelling or angioneurotic edema. Other milder allergic effects such as urticaria, itching, flushing, nausea, headache and musculoskeletal pain have also been observed, as have delayed hypersensitivity reactions such as vasculitis and interstitial nephritis. Anaphylactic shock was reported in one study with an incidence rate of 0.1%.
Mild or moderate allergic reactions may be managed with concomitant antihistamine and/or corticosteroid therapy. Severe allergic reactions require immediate discontinuation of Streptase®, Streptokinase, with adrenergic, antihistamine, and/or corticosteroid agents administered intravenously as required.

Fever
Although Streptase®, Streptokinase, is nonpyrogenic in standard animal tests, recent reports in the literature have noted an incidence of fever ranging from 0 to 21% in patients treated intravenously with Streptokinase. Symptomatic treatment is usually sufficient to alleviate discomfort. The use of acetaminophen rather than aspirin is preferable.

DOSAGE AND ADMINISTRATION
Acute Evolving Transmural Myocardial Infarction
Administer Streptokinase as soon as possible after onset of symptoms. The greatest benefit in mortality reduction was observed when Streptase®, Streptokinase, was administered within one hour, statistically significant benefits were observed up to six hours and some benefit was observed up to 12 hours without statistical significance (see CLINICAL PHARMACOLOGY in full prescribing information).

Route	Total Dose	Dosage/Duration
Intravenous infusion	1,500,000 IU	1,500,000 IU within 60 min.

HOW SUPPLIED
Streptase®, Streptokinase, is supplied as a lyophilized white powder in 50 mL infusion bottles (1,500,000 IU) or in 6.5 mL vials with a color-coded label corresponding to the amount of purified Streptokinase in each vial as follows:
green— 250,000 IU
blue — 750,000 IU
red — 1,500,000 IU vials and infusion bottles.
Store unopened vials at controlled room temperature (15°-30°C or 59°-86°F). Unused reconstituted drug should be discarded.

TRANDATE® Tablets
(labetalol hydrochloride)

BRIEF SUMMARY OF PRODUCT INFORMATION

The following is a brief summary only. Before prescribing, see complete prescribing information in TRANDATE® Tablets product labeling.

INDICATIONS AND USAGE: TRANDATE® Tablets are indicated in the management of hypertension. TRANDATE Tablets may be used alone or in combination with other antihypertensive agents, especially thiazide and loop diuretics.

CONTRAINDICATIONS: TRANDATE® Tablets are contraindicated in bronchial asthma, overt cardiac failure, greater-than-first-degree heart block, cardiogenic shock, and severe bradycardia (see **WARNINGS**).

WARNINGS: Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure. Beta-blockade carries a potential hazard of further depressing myocardial contractility and precipitating more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary labetalol HCl can be used with caution in patients with a history of heart failure who are well compensated. Congestive heart failure has been observed in patients receiving labetalol HCl. Labetalol HCl does not abolish the inotropic action of digitalis on heart muscle.

In Patients Without a History of Cardiac Failure: In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response should be observed closely. If cardiac failure continues despite adequate digitalization and diuretic, TRANDATE® therapy should be withdrawn (gradually, if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal: Angina pectoris has not been reported upon labetalol HCl discontinuation. However, hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered TRANDATE, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, TRANDATE administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue TRANDATE therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (eg, Chronic Bronchitis and Emphysema): Patients with bronchospastic disease should, in general, not receive beta-blockers. TRANDATE may be used with caution, however, in patients who do not respond to, or cannot tolerate, other antihypertensive agents. It is prudent, if TRANDATE is used, to use the smallest effective dose, so that inhibition of endogenous or exogenous beta-agonists is minimized.

Pheochromocytoma: Labetalol HCl has been shown to be effective in lowering blood pressure and relieving symptoms in patients with pheochromocytoma. However, paradoxical hypertensive responses have been reported in a few patients with this tumor; therefore, use caution when administering labetalol HCl to patients with pheochromocytoma.

Diabetes Mellitus and Hypoglycemia: Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (eg, tachycardia) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; it may therefore be necessary to adjust the dose of antidiabetic drugs.

Major Surgery: The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial. Protracted severe hypotension and difficulty in restarting or maintaining a heartbeat have been reported with beta-blockers. The effect of labetalol HCl's alpha-adrenergic activity has not been evaluated in this setting.

A synergism between labetalol HCl and halothane anesthesia has been shown (see **Drug Interactions** under **PRECAUTIONS**).

PRECAUTIONS: General: ***Impaired Hepatic Function:*** TRANDATE® Tablets should be used with caution in patients with impaired hepatic function since metabolism of the drug may be diminished.

Jaundice or Hepatic Dysfunction: On rare occasions, labetalol HCl has been associated with jaundice (both hepatic and cholestatic). It is therefore recommended that treatment with labetalol HCl be stopped immediately should a patient develop jaundice or laboratory evidence of liver injury. Both have been shown to be reversible on stopping therapy.

Information for Patients: As with all drugs with beta-blocking activity, certain advice to patients being treated with labetalol HCl is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects. While no incidence of the abrupt withdrawal phenomenon (exacerbation of angina pectoris) has been reported with labetalol HCl, dosing with TRANDATE Tablets should not be interrupted or discontinued without a physician's advice. Patients being treated with TRANDATE Tablets should consult a physician at any sign of impending cardiac failure. Also, transient scalp tingling may occur, usually when treatment with TRANDATE Tablets is initiated (see **ADVERSE REACTIONS**).

Laboratory Tests: As with any new drug given over prolonged periods, laboratory parameters should be observed over regular intervals. In patients with concomitant illnesses, such as impaired renal function, appropriate tests should be done to monitor these conditions.

Drug Interactions: In one survey, 2.3% of patients taking labetalol HCl in combination with tricyclic antidepressants experienced tremor as compared to 0.7% reported to occur with labetalol HCl alone. The contribution of each of the treatments to this adverse reaction is unknown, but the possibility of a drug interaction cannot be excluded.

Drugs possessing beta-blocking properties can blunt the bronchodilator effect of beta-receptor agonist drugs in patients with bronchospasm; therefore, doses greater than the normal antiasthmatic dose of beta-agonist bronchodilator drugs may be required.

Cimetidine has been shown to increase the bioavailability of labetalol HCl. Since this could be explained either by enhanced absorption or by an alteration of hepatic metabolism of labetalol HCl, special care should be used in establishing the dose required for blood pressure control in such patients.

Synergism has been shown between halothane anesthesia and intravenously administered labetalol HCl. During controlled hypotensive anesthesia using labetalol HCl in association with halothane, high concentrations (3% or above) of halothane should not be used because the degree of hypotension will be increased and because of the possibility of a large reduction in cardiac output and an increase in central venous pressure. The anesthesiologist should be informed when a patient is receiving labetalol HCl.

Labetalol HCl blunts the reflex tachycardia produced by nitroglycerin without preventing its hypotensive effect. If labetalol HCl is used with nitroglycerin in patients with angina pectoris, additional antihypertensive effects may occur.

Drug/Laboratory Test Interactions: The presence of a metabolite of labetalol in the urine may result in falsely increased levels of urinary catecholamines when measured by a nonspecific trihydroxyindole (THI) reaction. In screening patients suspected of having a pheochromocytoma and being treated with labetalol HCl, specific radioenzymatic or high performance liquid chromatography assay techniques should be used to determine levels of catecholamines or their metabolites.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term oral dosing studies with labetalol HCl for 18 months in mice and for two years in rats showed no evidence of carcinogenesis. Studies with labetalol HCl using dominant lethal assays in rats and mice and exposing microorganisms according to modified Ames tests showed no evidence of mutagenesis.

Pregnancy: ***Teratogenic Effects: Pregnancy Category C:*** Teratogenic studies have been performed with

labetalol in rats and rabbits at oral doses up to approximately six and four times the maximum recommended human dose (MRHD), respectively. No reproducible evidence of fetal malformations was observed. Increased fetal resorptions were seen in both species at doses approximating the MRHD. There are no adequate and well-controlled studies in pregnant women. Labetalol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nonteratogenic Effects: Infants of mothers who were treated with labetalol HCl during pregnancy did not appear to be adversely affected by the drug. Oral administration of labetalol to rats during late gestation through weaning at doses of two to four times the MRHD caused a decrease in neonatal survival.

Labor and Delivery: Labetalol HCl given to pregnant women with hypertension did not appear to affect the usual course of labor and delivery.

Nursing Mothers: Small amounts of labetalol (approximately 0.004% of the maternal dose) are excreted in human milk. Caution should be exercised when TRANDATE Tablets are administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects are mild, transient, and occur early in the course of treatment. In controlled clinical trials of three to four months' duration, discontinuation of TRANDATE® Tablets due to one or more adverse effects was required in 7% of all patients. In these same trials, beta-blocker control agents led to discontinuation in 8% to 10% of patients, and a centrally acting alpha-agonist in 30% of patients.

The following adverse reactions were derived from multi-center, controlled clinical trials over treatment periods of three and four months. The rates, which ranged from less than 1% to 5% except as otherwise noted, are based on adverse reactions considered probably drug-related by the investigator. If all reports are considered, the rates are somewhat higher (eg, dizziness, 20%; nausea, 14%; fatigue, 11%).

Body as a Whole: Fatigue, asthenia, and headache.
Gastrointestinal: Nausea (6%), vomiting, dyspepsia, diarrhea, and taste distortion.
Central and Peripheral Nervous Systems: Dizziness (11%), paresthesia, and drowsiness.
Autonomic Nervous System: Nasal stuffiness, ejaculation failure, impotence, and increased sweating.
Cardiovascular: Edema and postural hypotension.
Respiratory: Dyspnea.
Skin: Rash.
Special Senses: Vision abnormality and vertigo.

The adverse effects were reported spontaneously and are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, ie, a group excluding patients with bronchospastic disease, overt congestive heart failure, or other contraindications to beta-blocker therapy.

Clinical trials also included studies utilizing daily doses up to 2,400 mg in more severely hypertensive patients. The US therapeutic trials data base for adverse reactions that are clearly or possibly dose-related shows that the following side effects increased with increasing dose: dizziness, fatigue, nausea, vomiting, dyspepsia, paresthesia, nasal stuffiness, ejaculation failure, impotence, and edema.

In addition, a number of other less common adverse events have been reported in clinical trials or the literature:

Cardiovascular: Postural hypotension, including rarely, syncope.
Central and Peripheral Nervous Systems: Paresthesias, most frequently described as scalp tingling. In most cases, it was mild, transient, and usually occurred at the beginning of treatment.
Collagen Disorders: Systemic lupus erythematosus; positive antinuclear factor (ANF).
Eyes: Dry eyes.
Immunological System: Antimitochondrial antibodies.
Liver and Biliary System: Cholestasis with or without jaundice.
Musculoskeletal System: Muscle cramps; toxic myopathy.
Respiratory System: Bronchospasm.
Skin and Appendages: Rashes of various types, such as generalized maculopapular, lichenoid, urticarial, bullous lichen planus, psoriaform, and facial erythema; Peyronie's disease; reversible alopecia.
Urinary System: Difficulty in micturition, including acute urinary bladder retention.

Following approval for marketing in the United Kingdom, a monitored release survey involving approximately 6,800 patients was conducted for further safety and efficacy evaluation of this product. Results of this survey indicate that the type, severity, and incidence of adverse effects were comparable to those cited above.

Potential Adverse Effects: In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents.

Central Nervous System: Reversible mental depression progressing to catatonia, an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance or neuropsychometrics.
Cardiovascular: Intensification of AV block (see **CONTRAINDICATIONS**).
Allergic: Fever combined with aching and sore throat; laryngospasm; respiratory distress.
Hematologic: Agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura.
Gastrointestinal: Mesenteric artery thrombosis; ischemic colitis.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with labetalol HCl.

Clinical Laboratory Tests: There have been reversible increases of serum transaminases in 4% of patients treated with labetalol HCl and tested, and more rarely, reversible increases in blood urea.

OVERDOSAGE: Information concerning possible overdosage and its treatment appears in the full prescribing information.

DOSAGE AND ADMINISTRATION: DOSAGE MUST BE INDIVIDUALIZED. The recommended *initial* dosage is 100 mg *twice* daily whether used alone or added to a diuretic regimen. After two or three days, using standing blood pressure as an indicator, dosage may be titrated in increments of 100 mg bid every two or three days. The usual *maintenance* dosage of labetalol HCl is between 200 and 400 mg *twice* daily. Before use, see complete prescribing information for dosage details.

HOW SUPPLIED: TRANDATE® Tablets, 100 mg, light orange, round, scored, film-coated tablets engraved on one side with "TRANDATE 100 GLAXO," bottles of 100 (NDC 0173-0346-43) and 500 (NDC 0173-0346-44) and unit dose packs of 100 tablets (NDC 0173-0346-47).

TRANDATE Tablets, 200 mg, white, round, scored, film-coated tablets engraved on one side with "TRANDATE 200 GLAXO," bottles of 100 (NDC 0173-0347-43) and 500 (NDC 0173-0347-44) and unit dose packs of 100 tablets (NDC 0173-0347-47).

TRANDATE Tablets, 300 mg, peach, round, scored, film-coated tablets engraved on one side with "TRANDATE 300 GLAXO," bottles of 100 (NDC 0173-0348-43) and 500 (NDC 0173-0348-44) and unit dose packs of 100 tablets (NDC 0173-0348-47).

TRANDATE Tablets should be stored between 2° and 30°C (36° and 86°F). TRANDATE Tablets in the unit dose boxes should be protected from excessive moisture.

617 Effect of Increasing Heart Rate on Left Ventricular Performance in Patients with Normal Cardiac Function

Saul Schaefer, Anne L. Taylor, Howard R. Lee, Elaine H. Niggemann, Benjamin D. Levine, Jeffrey J. Popma, Jere H. Mitchell, and L. David Hillis

In 19 patients with normal left ventricular (LV) function and coronary arteries, LV dP/dt max was measured at baseline heart rate and during incremental atrial pacing. In the 10 patients in whom intravascular volume was not altered during pacing, dP/dt max increased modestly (13 ± 16%); in contrast, in the 9 in whom normal saline was infused during pacing to maintain a constant LV preload, dP/dt max increased substantially (36 ± 17%) ($p = 0.007$). Thus, an increase in heart rate induces a modest increase in LV dP/dt max in patients in whom LV preload is allowed to decrease, whereas it causes a marked increase in dP/dt max in those in whom LV preload is maintained.

621 Intrinsic Left Ventricular Contractility in Normal Subjects

Marvin W. Kronenberg, Jack P. Uetrecht, William D. Dupont, Michael H. Davis, Brian K. Phelan, and Gottlieb C. Friesinger

The influence of autonomic tone and exercise stress on left ventricular (LV) contractility was assessed in 12 normal subjects using the relation of peak-systolic pressure to end-systolic volume (pressure-volume relation) and the ratio of peak-systolic pressure to end-systolic volume (pressure/volume ratio). Cuff blood pressure and gated equilibrium radionuclide ventriculography were employed at rest, during exercise and during pharmacologic pressure-afterloading with phenylephrine, both before and after vagal and β-adrenergic "blockade." Both the pressure/volume ratio and ejection fraction increased on exercise ($p \leq 0.008$). The pressure-volume relations were linear after blockade and there was no systematic difference in the slope of pressure-volume relations induced by blockade. Serial studies in 6 subjects showed no significant differences. Thus, vagal and β-adrenergic tone are not important for supporting LV contractility in normal subjects. The reproducibility of the measurements supports the feasibility of serial studies of contractility.

628 Strategies for Increasing Early Adherence to and Long-Term Maintenance of Home-Based Exercise Training in Healthy Middle-Aged Men and Women

Abby C. King, C. Barr Taylor, William L. Haskell, and Robert F. DeBusk

Strategies for the adoption and maintenance of moderate-intensity, home-based exercise training were evaluated in 52 men and 51 women who had participated in a 6-month-long randomized trial of moderate-intensity, home-based exercise training. The adoption study compared 2 levels of intensity of staff support. Among subjects adopting exercise for the first time, functional capacity increased significantly only in those receiving more intensive staff support. The maintenance study compared

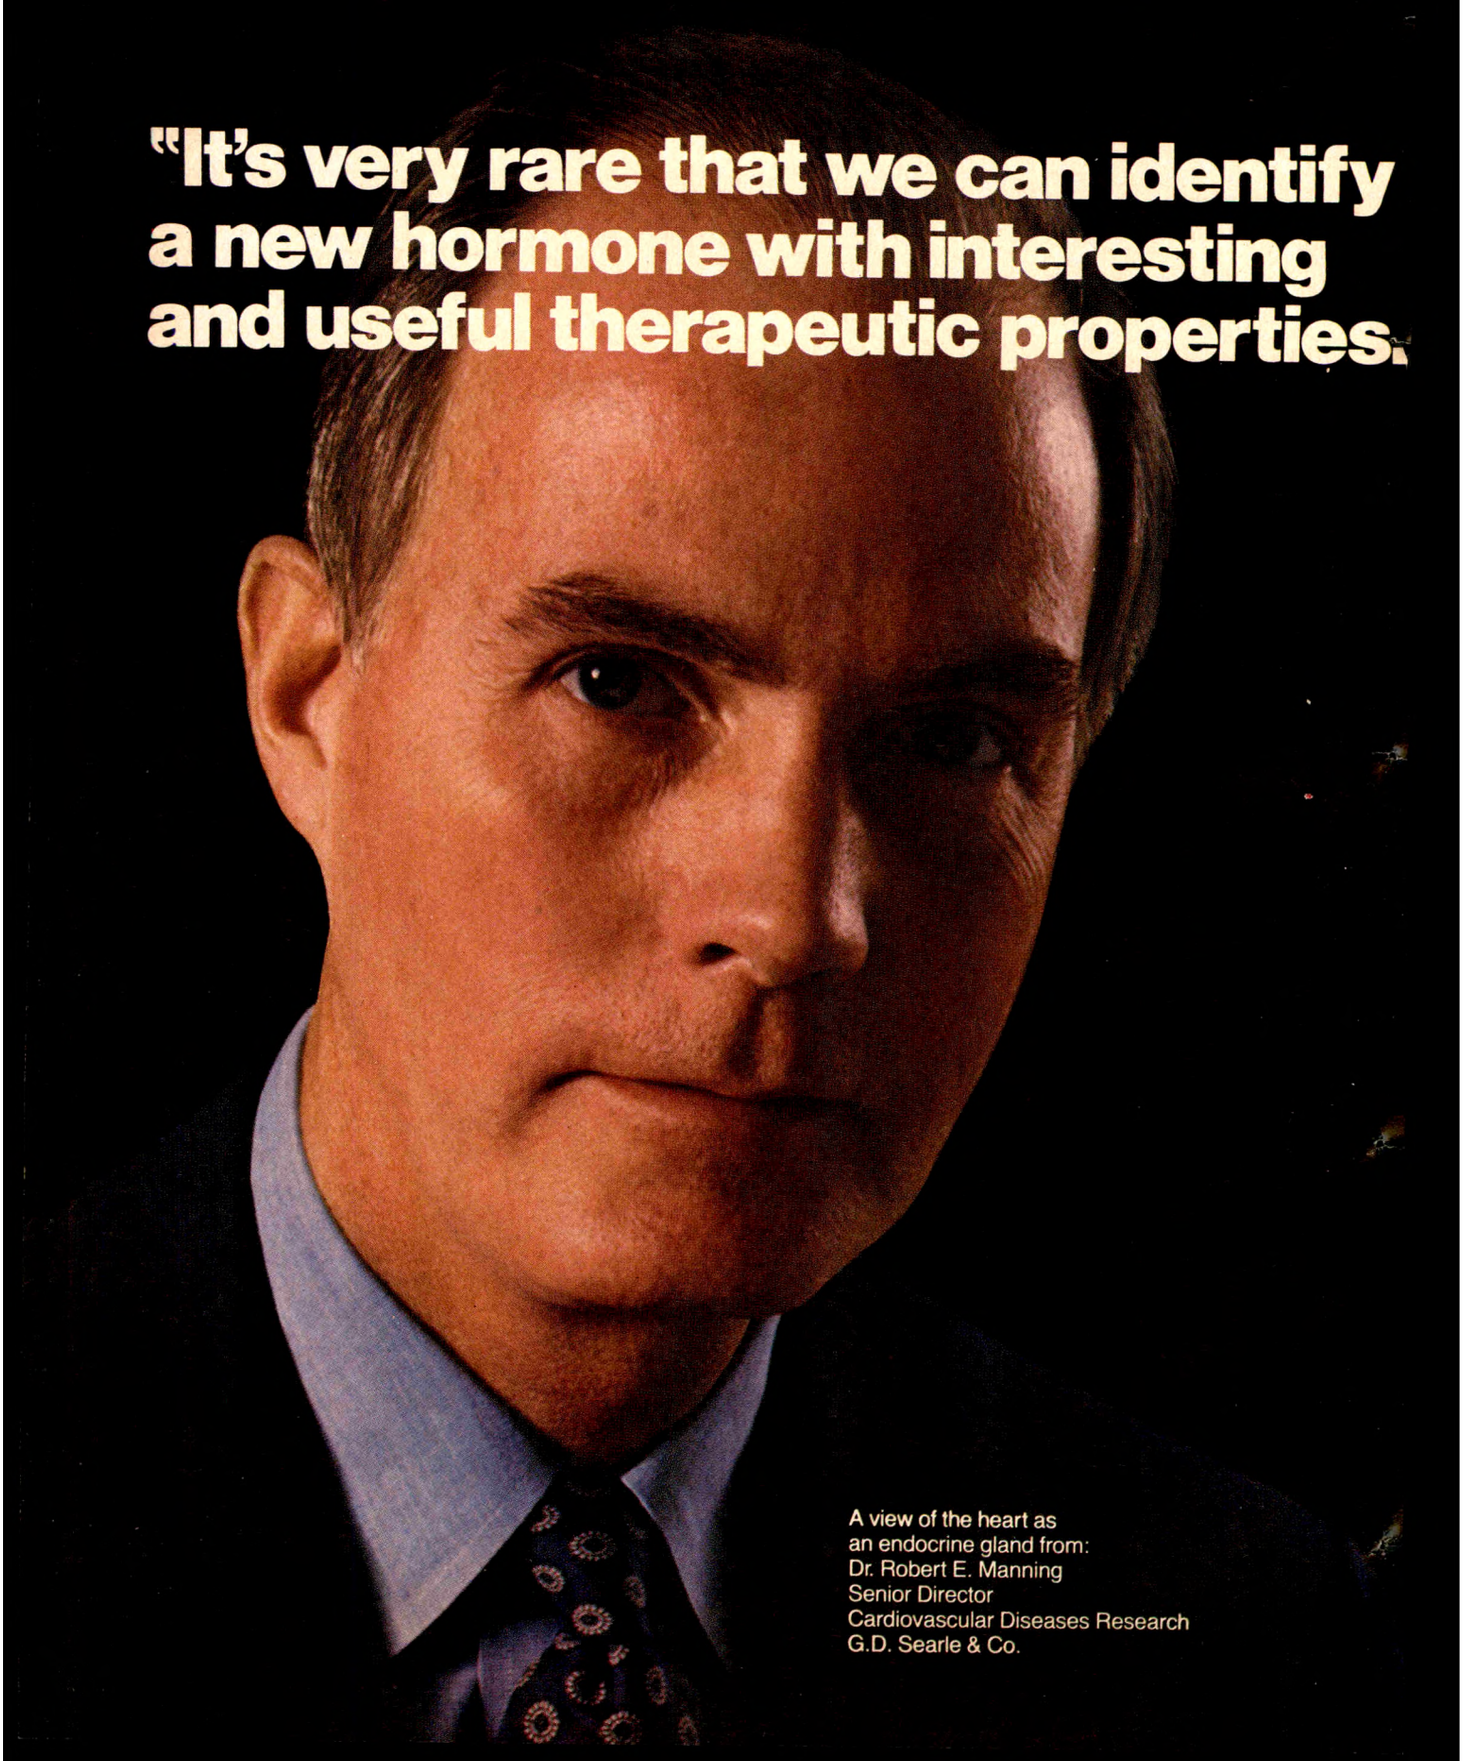
THE NEW VISION OF

"It's very rare that we can identify a new hormone with interesting and useful therapeutic properties.



A view of the heart as
an endocrine gland from:
Dr. Robert E. Manning
Senior Director
Cardiovascular Diseases Research
G.D. Searle & Co.

RESEARCH FROM SEARLE

Atrial peptides fill that bill."

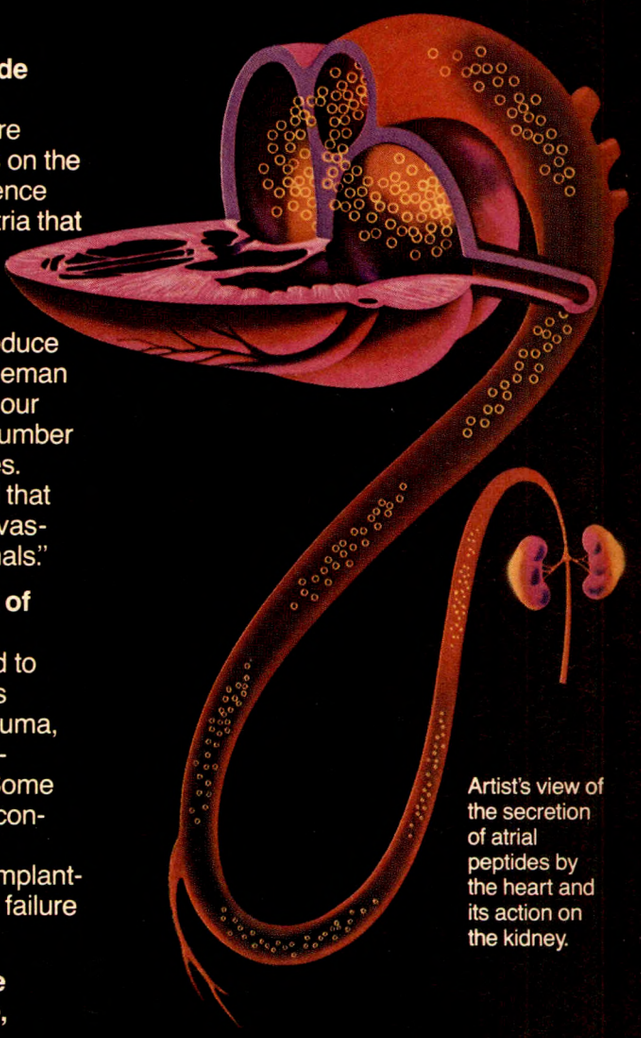
"We have been actively involved in atrial peptide research from the outset."
"The atrial peptides appear to be hormones that are released from the heart and have profound effects on the cardiovascular system. The first clue to their existence came from the discovery of small bodies in both atria that looked like secretory granules. The density of these granules was shown to vary with changes in sodium and water balance.

"Extracts of atrium were demonstrated to produce a marked diuresis in rats. This led Dr. Philip Needleman and his associates to enter into collaboration with our peptide chemists. We worked together—as did a number of other groups—to isolate a family of atrial peptides. The circulating form is a 28-amino acid compound that causes diuresis, natriuresis, relaxation of isolated vascular strips and lowering of blood pressure in animals."

"Atrial peptides may be useful in the treatment of acute renal failure."
"Certain of the atrial peptides have been observed to cause a selective renal vasodilation. This suggests their possible use in renal shutdown caused by trauma, abdominal surgery, suprarenal aortic clamping, immunosuppressant therapy and hepatic cirrhosis. Some of these disease states are characterized by vasoconstriction.

"Continuous administration by some sort of implantable pump might have major value in chronic renal failure and postpone the need for dialysis."

"Even more important, atrial peptides could be natural hormonal regulators of blood pressure, blood volume and electrolyte balance."
"Hopefully, this concept may lead us to related therapeutic agents that could be orally administered and would have a long duration of action. Such agents could have significant potential for the treatment of hypertension, congestive heart failure, and a number of fluid and electrolyte disorders."



Artist's view of the secretion of atrial peptides by the heart and its action on the kidney.

ADD CAPOTEN® SOONER*...

(captopril tablets)

SQUIBB

COMPLETE THE JOB YOUR LOOP DIURETIC STARTED

In patients symptomatic on diuretic and digitalis

- ☐ Adding CAPOTEN enhances the diuretic effect of furosemide
  —Disappearance of edema in 55% of a subgroup of patients after adding CAPOTEN to furosemide†[1]
- ☐ Adding CAPOTEN improves exercise tolerance times in mild, moderate, and severe heart failure patients[2]

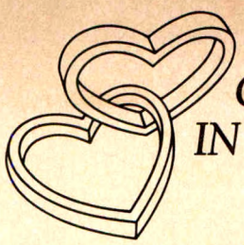
IN MILD, MODERATE, AND SEVERE HEART FAILURE (NYHA Class II, III, and IV)

CAPOTEN®
(captopril tablets)

CLOSING THE LOOP IN HEART FAILURE THERAPY

*CAPOTEN is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis. In using CAPOTEN, consideration should be given to the risk of neutropenia/agranulocytosis. Use special precautions in patients with impaired renal function, collagen vascular disorders, or those exposed to other drugs known to affect the white cells or immune response. Evaluation of heart failure patients should always include assessment of renal function. See INDICATIONS AND USAGE, CONTRAINDICATIONS, WARNINGS, and ADVERSE REACTIONS in the brief summary of prescribing information on adjacent page.

†Patients for whom data were available for two months. Patients were NYHA Class II, III, or IV receiving concomitant diuretic and digitalis therapy.



CLOSING THE LOOP IN HEART FAILURE THERAPY

SQUIBB

CAPOTEN® TABLETS
Captopril Tablets

INDICATIONS: Hypertension – CAPOTEN (captopril) is indicated for the treatment of hypertension. Consideration should be given to the risk of neutropenia/agranulocytosis (see WARNINGS). CAPOTEN may be used as initial therapy for patients with normal renal function, in whom the risk is relatively low. In patients with impaired renal function, particularly those with collagen vascular disease, captopril should be reserved for those who have either developed unacceptable side effects on other drugs, or have failed to respond satisfactorily to drug combinations. CAPOTEN is effective alone and in combination with other antihypertensive agents, especially thiazide-type diuretics.

Heart Failure: CAPOTEN (captopril) is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.

CONTRAINDICATIONS: CAPOTEN is contraindicated in patients who are hypersensitive to this product.

WARNINGS: Neutropenia/Agranulocytosis – Neutropenia ($< 1000/mm^3$) with myeloid hypoplasia has resulted from use of captopril. About half of the neutropenic patients developed systemic or oral cavity infections or other features of the syndrome of agranulocytosis. The risk of neutropenia is dependent on the clinical status of the patient:

In clinical trials in patients with hypertension who have normal renal function (serum creatinine less than 1.6 mg/dL and no collagen vascular disease), neutropenia has been seen in one patient out of over 8,600 exposed. In patients with some degree of renal failure (serum creatinine at least 1.6 mg/dL) but no collagen vascular disease, the risk in clinical trials was about 1 per 500. Doses were relatively high in these patients, particularly in view of their diminished renal function. In patients with collagen vascular diseases (e.g., systemic lupus erythematosus, scleroderma) and impaired renal function, neutropenia occurred in 3.7% of patients in clinical trials. While none of the over 750 patients in formal clinical trials of heart failure developed neutropenia, it has occurred during the subsequent clinical experience. Of reported cases, about half had serum creatinine ≥ 1.6 mg/dL and more than 75% received procainamide. In heart failure, it appears that the same risk factors for neutropenia are present.

Neutropenia has appeared usually within 3 months after starting therapy, associated with myeloid hypoplasia and frequently accompanied by erythroid hypoplasia and decreased numbers of megakaryocytes (e.g., hypoplastic bone marrow and pancytopenia); anemia and thrombocytopenia were sometimes seen. Neutrophils generally returned to normal in about 2 weeks after captopril was discontinued, and serious infections were limited to clinically complex patients. About 13% of the cases of neutropenia have ended fatally, but almost all fatalities were in patients with serious illness, having collagen vascular disease, renal failure, heart failure or immunosuppressant therapy, or a combination of these complicating factors. **Evaluation of the hypertensive or heart failure patient should always include assessment of renal function.** If captopril is used in patients with impaired renal function, white blood cell and differential counts should be evaluated prior to starting treatment and at approximately 2-week intervals for about 3 months, then periodically. In patients with collagen vascular disease or who are exposed to other drugs known to affect the white cells or immune response, particularly when there is impaired renal function, captopril should be used only after an assessment of benefit and risk, and then with caution. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat, fever). If infection is suspected, perform white cell counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count $< 1000/mm^3$) withdraw captopril and closely follow the patient's course.

Proteinuria: Total urinary proteins >1 g per day were seen in about 0.7% of patients on captopril. About 90% of affected patients had evidence of prior renal disease or received high doses (>150 mg/day), or both. The nephrotic syndrome occurred in about one-fifth of proteinuric patients. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued. The BUN and creatinine were seldom altered in proteinuric patients. Since most cases of proteinuria occurred by the 8th month of therapy with captopril, patients with prior renal disease or those receiving captopril at doses >150 mg per day, should have urinary protein estimates (dip-stick on 1st morning urine) before therapy, and periodically thereafter.

Hypotension: Excessive hypotension was rarely seen in hypertensive patients but is a possibility in severely salt/volume-depleted persons such as those treated vigorously with diuretics (see PRECAUTIONS [Drug Interactions]). In heart failure, where the blood pressure was either normal or low, transient decreases in mean blood pressure >20% were recorded in about half of the patients. This transient hypotension may occur after any of the first several doses and is usually well tolerated, although rarely it has been associated with arrhythmia or conduction defects. A starting dose of 6.25 or 12.5 mg tid may minimize the hypotensive effect. Patients should be followed closely for the first 2 weeks of treatment and whenever the dose of captopril and/or diuretic is increased.

BECAUSE OF THE POTENTIAL FALL IN BLOOD PRESSURE IN THESE PATIENTS, THERAPY SHOULD BE STARTED UNDER VERY CLOSE MEDICAL SUPERVISION.

PRECAUTIONS: General: *Impaired Renal Function* – Hypertension – Some hypertensive patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible. Heart Failure – About 20% of patients develop stable elevations of BUN and serum creatinine >20% above normal or baseline upon long-term treatment. Less than 5% of patients, generally with severe preexisting renal disease, required discontinuation due to progressively increasing creatinine. See DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]. *Valvular Stenosis* – A theoretical concern, for risk of decreased coronary perfusion, has been noted regarding vasodilator treatment in patients with aortic stenosis due to decreased afterload reduction. *Surgery/Anesthesia* – If hypotension occurs during surgery or anesthesia, and is considered due to the effects of captopril, it is correctable by volume expansion.

Drug Interactions: *Hypotension – Patients on Diuretic Therapy* – Precipitous reduction of blood pressure may occasionally occur within the 1st hour after administration of the initial of captopril dose in patients on diuretics, especially those recently placed on diuretics, and those on severe dietary salt restriction or dialysis. This possibility can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy or by initiating therapy with small doses (6.25 or 12.5 mg). Alternatively, provide medical supervision for at least 1 hour after the initial dose.

Agents Having Vasodilator Activity – In heart failure patients, vasodilators should be administered with caution.

Agents Causing Renin Release – Captopril's effect will be augmented by antihypertensive agents that cause renin release.

Agents Affecting Sympathetic Activity – The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

Agents Increasing Serum Potassium – Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium. Use potassium-containing salt substitutes with caution.

Inhibitors of Endogenous Prostaglandin Synthesis – Indomethacin and other nonsteroidal anti-inflammatory agents may reduce the antihypertensive effect of captopril, especially in low renin hypertension.

Drug/Laboratory Test Interaction: Captopril may cause a false-positive urine test for acetone.

Carcinogenesis, Mutagenesis and Impairment of Fertility: Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential. Studies in rats have revealed no impairment of fertility.

Pregnancy: Category C: There are no adequate and well-controlled studies in pregnant women. Embryocidal effects and craniofacial malformations were observed in rabbits. Therefore, captopril should be used during pregnancy, or for patients likely to become pregnant, only if the potential benefit outweighs the potential risk to the fetus. Captopril crosses the human placenta.

Nursing Mothers: Captopril is secreted in human milk. Exercise caution when administering captopril to a nursing woman, and, in general, nursing should be interrupted.

Pediatric Use: Safety and effectiveness in children have not been established although there is limited experience with use of captopril in children from 2 months to 15 years of age. Dosage, on a weight basis, was comparable to that used in adults. CAPOTEN (captopril) should be used in children only if other measures for controlling blood pressure have not been effective.

ADVERSE REACTIONS: Reported incidences are based on clinical trials involving approximately 7000 patients.

Renal – About 1 of 100 patients developed proteinuria (see WARNINGS). Renal insufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patients.

Hematologic – Neutropenia/agranulocytosis has occurred (see WARNINGS). Anemia, thrombocytopenia, and pancytopenia have been reported.

Dermatologic – Rash, (usually maculopapular, rarely urticarial), often with pruritus, and sometimes with fever and eosinophilia, in about 4 to 7 of 100 patients (depending on renal status and dose), usually during the 1st 4 weeks of therapy. Pruritus, without rash, in about 2 of 100 patients. A reversible associated pemphigoid-like lesion, and photosensitivity, have also been reported. Angioedema of the face, mucous membranes of the mouth, or of the extremities in about 1 of 1000 patients – reversible on discontinuance of captopril therapy. One case of laryngeal edema has been reported. Flushing or pallor in 2 to 5 of 1000 patients.

Cardiovascular – Hypotension may occur; see WARNINGS and PRECAUTIONS [Drug Interactions] for discussion of hypotension on initiation of captopril therapy. Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocardial infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 1000 patients.

Dysgeusia – Approximately 2 to 4 (depending on renal status and dose) of 100 patients developed a diminution or loss of taste perception; taste impairment is reversible and usually self-limited even with continued drug use (2 to 3 months). Gastric irritation, abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulcers, peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, cough, alopecia, paresthesias reported in about 0.5 to 2% of patients but did not appear at increased frequency compared to placebo or other treatments used in controlled trials.

Altered Laboratory Findings: Elevations of liver enzymes in a few patients although no causal relationship has been established. Rarely cholestatic jaundice, and hepatocellular injury with or without secondary cholestasis, have been reported. A transient elevation of BUN and serum creatinine may occur, especially in volume-depleted or renovascular hypertension patients. In instances of rapid reduction of longstanding or severely elevated blood pressure, the glomerular filtration rate may decrease transiently, also resulting in transient rises in serum creatinine and BUN. Small increases in serum potassium concentration frequently occur, especially in patients with renal impairment (see PRECAUTIONS).

OVERDOSAGE: Primary concern is correction of hypotension. Volume expansion with an I.V. infusion of normal saline is the treatment of choice for restoration of blood pressure. Captopril may be removed from the general circulation by hemodialysis.

DOSAGE AND ADMINISTRATION: CAPOTEN (captopril) should be taken one hour before meals. In hypertension, CAPOTEN may be dosed bid or tid. Dosage must be individualized; see DOSAGE AND ADMINISTRATION section of package insert for detailed information regarding dosage in hypertension and in heart failure. Because CAPOTEN (captopril) is excreted primarily by the kidneys, dosage adjustments are recommended for patients with impaired renal function.

Consult package insert before prescribing CAPOTEN (captopril).

HOW SUPPLIED: Available in tablets of 12.5, 25, 50, and 100 mg in bottles of 100 (25 mg and 50 mg also available in bottles of 1000), and in UNIMATIC® unit-dose packs of 100 tablets. (J3-658J)

FEATURES

Simultaneous two-channel analysis of ECG events

Analysis of full-sized strips including:

- Time and date
- Duration of episode
- Heart rate at onset
- Correlation with symptoms

Rapid report generation

Comprehensive hard copy report includes:

- ST deviations—maximum depressions and elevations displayed
- Pauses
- Ventricular ectopy
  - — VPBs
  - — Couplets
  - — V-tach
- Bradycardia
- Tachycardia
- Patient event marker samples
- Routine and automatic sampling of the ECG
- Histograms
- Quantitative data
- Narrative summary

ONCE-A-DAY
Calan® SR
(verapamil HCl) 240mg
SUSTAINED-RELEASE CAPLETS

- **Convenient one-caplet, once-a-day dosing regimen:* Start with one 240—mg caplet in the morning with food. (Starting dosages of 120 mg/day, ½ caplet, may be suitable for the elderly or those of small stature.)**
- **Favorably priced—similar in cost to beta blockers**

*Some patients may require *b.i.d.* dosing.

BRIEF SUMMARY

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure<90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block (if no pacemaker is present).

Warnings: Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction<30%) or moderate to severe symptoms of cardiac failure and in patients with significant ventricular dysfunction if they are receiving a beta-adrenergic blocker. Control milder heart failure with optimum digitalization and/or diuretics before Calan SR is used. Verapamil may occasionally produce a decrease in blood pressure below normal levels, which may result in dizziness or symptomatic hypotension. Elevations of liver enzymes have been reported. Several cases of hepatocellular injury have been demonstrated to be produced by verapamil. Periodic monitoring of liver function in patients on verapamil is prudent. Some patients with paroxysmal and/or chronic atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) have developed an increased antegrade conduction across the accessory pathway bypassing the AV node, producing a very rapid ventricular response or ventricular fibrillation after receiving I.V. verapamil (or digitalis). The effect of verapamil on AV conduction and the SA node may cause asymptomatic 1st-degree AV block and transient bradycardia, sometimes with nodal escape rhythms. PR-interval prolongation is correlated with verapamil plasma concentrations especially during initial titration. Higher degrees of AV block are infrequent (0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil.

Precautions: Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Verapamil may decrease neuromuscular transmission in patients with Duchenne's muscular dystrophy and may prolong recovery from the neuromuscular blocking agent vecuronium. It may be necessary to decrease verapamil dosage in patients with attenuated neuromuscular transmission. Studies in a small number of patients suggest that concomitant use of Calan and oral beta-adrenergic blockers may be beneficial in certain patients with chronic stable angina or hypertension. Combined therapy can also have adverse effects on cardiac function; therefore patients should be closely monitored. A decrease in metoprolol clearance may occur with concurrent use of verapamil and metoprolol. Chronic verapamil treatment increases serum digoxin levels by 50% to 75% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient reassessed. Verapamil used concomitantly with oral antihypertensive agents will usually have an additive effect on lowering blood pressure that in some cases may be excessive; therefore patients should be monitored appropriately. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Quinidine levels may increase during verapamil therapy. Clearance of verapamil may be reduced in concomitant use with cimetidine. Concomitant use of verapamil and lithium may result in decreased serum lithium levels. Verapamil therapy may increase carbamazepine concentrations during combined use. Therapy with rifampin may markedly reduce oral verapamil bioavailability. Concomitant use of inhalation anesthetics and calcium antagonists needs careful titration to avoid excessive cardiovascular depression. Verapamil may potentiate the activity of neuromuscular blocking agents (curare-like and depolarizing); dosage reduction may be required. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Another study in rats showed no evidence of carcinogenicity. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. Verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use. Safety and efficacy in children under 18 have not been established.

Adverse Reactions— oral verapamil: Constipation (8.4%), dizziness (3.5%), nausea (2.7%), hypotension (2.5%), edema (2.1%), headache (1.9%), CHF/pulmonary edema (1.8%), fatigue (1.7%), bradycardia: HR <50/min (1.4%), AV block: total 1°, 2°, 3° (1.3%)/3rd-degree (0.8%), flushing (0.1%); elevations of liver enzymes have been reported (see *Warnings*). The following reactions, reported in 1.0% or less of patients, occurred under circumstances where a causal relationship is not certain: angina pectoris, chest pain, claudication, myocardial infarction, palpitations, purpura (vasculitis), syncope, diarrhea, dry mouth, gastrointestinal distress, gingival hyperplasia, ecchymosis or bruising, cerebrovascular accident, confusion, equilibrium disorders, insomnia, muscle cramps, paresthesia, psychotic symptoms, shakiness, somnolence, dyspnea, arthralgia, rash, exanthema, hair loss, hyperkeratosis, macules, sweating, urticaria, blurred vision, gynecomastia, impotence, increased urination, spotty menstruation.

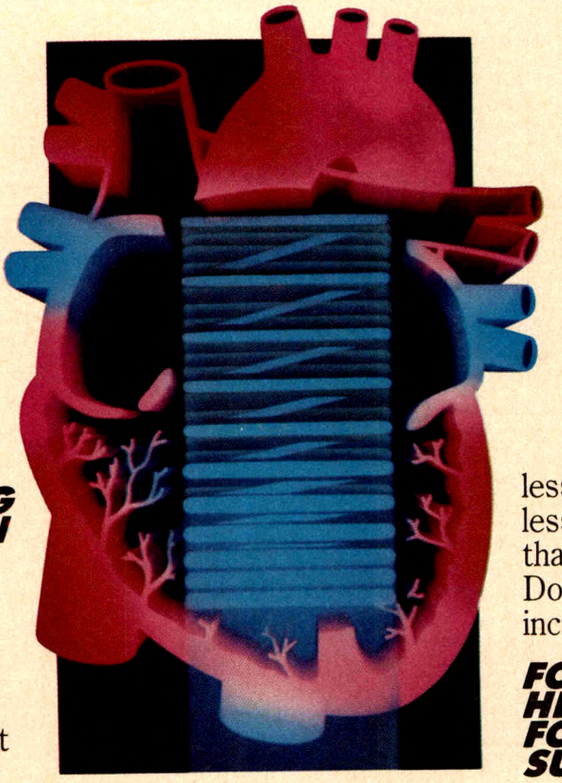
ADD INOTROPIC FORCE



WITHOUT INDUCING VASOCONSTRICTION

Dobutrex is a myocardial stimulant with virtually no vasoconstrictor effects. It works directly to increase myocardial contractility in patients suffering from heart failure.

FOR PATIENTS WITH ACUTE CONGESTIVE HEART FAILURE

Dobutrex quickly increases cardiac output, stroke volume, and organ perfusion. At the same time, Dobutrex reduces left ventricular filling pressure and systemic resistance, with little increase in heart rate.*

FOR PATIENTS WITH HEART FAILURE SECONDARY TO ACUTE MI

For MI patients who are not hypotensive or who have elevated filling pressures... Dobutrex maintains perfusion pressure by increasing cardiac output and decreasing vascular resistance.

Blood and oxygen are supplied to the myocardium in proportion to demand—with less increase in heart rate and less potential for arrhythmias than other catecholamines. Dobutrex does not significantly increase blood pressure.*

FOR PATIENTS WITH HEART FAILURE FOLLOWING CARDIAC SURGERY

Dobutrex improves the contractility of the depressed myocardium following cardiac surgery.

Afterload decreases in proportion with increases of cardiac output. As a result, Dobutrex reduces the risk of pulmonary edema and post-operative hypertension.

*Excess dosage of dobutamine may produce unwanted alterations in blood pressure, heart rate, or ventricular ectopic activity.

Dobutrex® Solution

dobutamine hydrochloride injection

Brief Summary. Consult the package insert for prescribing information.

Clinical Pharmacology: Dobutrex Solution is a direct-acting inotropic agent whose primary activity results from stimulation of the ß receptors of the heart while producing comparatively mild chronotropic, hypertensive, arrhythmogenic, and vasodilative effects. It does not cause the release of endogenous norepinephrine, as does dopamine. In animal studies, dobutamine produces less increase in heart rate and less decrease in peripheral vascular resistance for a given inotropic effect than does isoproterenol.

In patients with depressed cardiac function, both dobutamine and isoproterenol increase the cardiac output to a similar degree. In the case of dobutamine, this increase is usually not accompanied by marked increases in heart rate (although tachycardia is occasionally observed), and the cardiac stroke volume is usually increased. In contrast, isoproterenol increases the cardiac index primarily by increasing the heart rate while stroke volume changes little or declines.

Facilitation of atrioventricular conduction has been observed in human electrophysiologic studies and in patients with atrial fibrillation.

Systemic vascular resistance is usually decreased with administration of dobutamine. Occasionally, minimum vasoconstriction has been observed.

Most clinical experience with dobutamine is short-term—up to several hours in duration. In the limited number of patients who were studied for 24, 48, and 72 hours, a persistent increase in cardiac output occurred in some, whereas the output of others returned toward baseline values.

The onset of action of Dobutrex Solution is within one to two minutes; however, as much as ten minutes may be required to obtain the peak effect of a particular infusion rate.

The plasma half-life of dobutamine in humans is two minutes. The principal routes of metabolism are methylation of the catechol and conjugation. In human urine, the major excretion products are the conjugates of dobutamine and 3-O-methyl dobutamine. The 3-O-methyl derivative of dobutamine is inactive.

Alteration of synaptic concentrations of catecholamines with either reserpine or tricyclic antidepressants does not alter the actions of dobutamine in animals, which indicates that the actions of dobutamine are not dependent on presynaptic mechanisms.

Indications and Usage: Dobutrex Solution is indicated when parenteral therapy is necessary for inotropic support in the short-term treatment of adults with cardiac decompensation due to depressed contractility resulting either from organic heart disease or from cardiac surgical procedures.

In patients who have atrial fibrillation with rapid ventricular response, a digitalis preparation should be used prior to institution of therapy with Dobutrex.

Contraindications: Dobutrex Solution is contraindicated in patients with idiopathic hypertrophic subaortic stenosis and in patients who have shown previous manifestations of hypersensitivity to Dobutrex.

Warnings: 1. *Increase in Heart Rate or Blood Pressure*—Dobutrex Solution may cause a marked increase in heart rate or blood pressure, especially systolic pressure. Approximately 10% of patients in clinical studies have had rate increases of 30 beats/minute or more, and about 7.5% have had a 50-mm Hg or greater increase in systolic pressure. Reduction of dosage usually reverses these effects promptly. Because dobutamine facilitates atrioventricular conduction, patients with atrial fibrillation are at risk of developing rapid ventricular response. Patients with preexisting hypertension appear to face an increased risk of developing an exaggerated pressor response.

2. *Ectopic Activity*—Dobutrex Solution may precipitate or exacerbate ventricular ectopic activity, but it rarely has caused ventricular tachycardia.

3. *Hypersensitivity*—Reactions suggestive of hypersensitivity associated with administration of Dobutrex Solution, including skin rash, fever, eosinophilia, and bronchospasm, have been reported occasionally.

4. Dobutrex Solution contains sodium bisulfite, a sulfite that may cause allergic-type reactions, including anaphylactic symptoms and life-threatening or less severe asthmatic episodes, in certain susceptible people. The overall prevalence of sulfite sensitivity in the general population is unknown and probably low. Sulfite sensitivity is seen more frequently in asthmatic than in nonasthmatic people.

Precautions: 1. During the administration of Dobutrex Solution, as with any adrenergic agent, ECG and blood pressure should be continuously monitored. In addition, pulmonary wedge pressure and cardiac output should be monitored whenever possible to aid in the safe and effective infusion of Dobutrex Solution.

2. Hypovolemia should be corrected with suitable volume expanders before treatment with Dobutrex Solution is instituted.

3. Animal studies indicate that dobutamine may be ineffective if the patient has recently received a ß-blocking drug. In such a case, the peripheral vascular resistance may increase.

4. No improvement may be observed in the presence of marked mechanical obstruction, such as severe valvular aortic stenosis.

Usage Following Acute Myocardial Infarction—Clinical experience with Dobutrex Solution following myocardial infarction has been insufficient to establish the safety of the drug for this use. There is concern that any agent which increases contractile force and heart rate may increase the size of an infarction by intensifying ischemia, but it is not known whether dobutamine does so.

Usage in Pregnancy—Reproduction studies performed in rats and rabbits have revealed no evidence of impaired fertility, harm to the fetus, or teratogenic effects due to dobutamine. However, the drug has not been administered to pregnant women and should be used only when the expected benefits clearly outweigh the potential risks to the fetus.

Pediatric Use—The safety and effectiveness of Dobutrex Solution for use in children have not been studied.

Drug Interactions—There was no evidence of drug interactions in clincial studies in which Dobutrex Solution was administered concurrently with other drugs, including digitalis preparations, furosemide, spironolactone, lidocaine, glyceryl trinitrate, isosorbide dinitrate, morphine, atropine, heparin, protamine, potassium chloride, folic acid, and acetaminophen. Preliminary studies indicate that the concomitant use of dobutamine and nitroprusside results in a higher cardiac output and, usually, a lower pulmonary wedge pressure than when either drug is used alone.

Adverse Reactions: *Increased Heart Rate, Blood Pressure, and Ventricular Ectopic Activity*—A 10- to 20-mm increase in systolic blood pressure and an increase in heart rate of 5 to 15 beats/minute have been noted in most patients. (*See* Warnings regarding exaggerated chronotropic and pressor effects.) Approximately 5% of patients have had increased premature ventricular beats during infusions. These effects are dose related.

Miscellaneous Uncommon Effects—The following adverse effects have been reported in 1 to 3% of patients: nausea, headache, anginal pain, nonspecific chest pain, palpitations, and shortness of breath.

No abnormal laboratory values attributable to Dobutrex Solution have been observed.

Longer-Term Safety—Infusions of up to 72 hours have revealed no adverse effects other than those seen with shorter infusions.

Overdosage: In case of overdosage, as evidenced by excessive alteration of blood pressure or by tachycardia, reduce the rate of administration or temporarily discontinue Dobutrex Solution until the patient's condition stabilizes. Because the duration of action of Dobutrex Solution is short, usually no additional remedial measures are necessary.

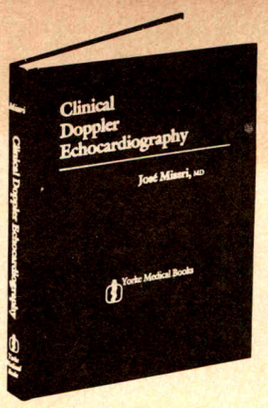
...a comprehensive text emphasizing the clinical aspects of Doppler echocardiography



Clinical Doppler Echocardiography

by José Missri, MD

0-914316-51-6 256 pp., April 1986, 175 illustrations, $55.00

The development and refinement of Doppler echocardiography represent a major advance in the diagnostic applications of ultrasound in heart disease.

Dr. Missri has written *Clinical Doppler Echocardiography* to provide clinical cardiologists, postdoctoral fellows and "echo" technologists with practical information on cardiac Doppler applied to acquired and congenital disease.

Clearly written, logically presented, generously illustrated—including 4-color examples of Doppler color-flow mapping—and thoroughly indexed, *Clinical Doppler Echocardiography* is a must addition for personal and medical center libraries.

Table of Contents (in brief)

INTRODUCTION TO DOPPLER ECHOCARDIOGRAPHY
PRINCIPLES OF DOPPLER ECHOCARDIOGRAPHY AND INSTRUMENTATION
DOPPLER EXAMINATION OF THE HEART AND GREAT VESSELS
DOPPLER EVALUATION OF MITRAL VALVE DISEASE
DOPPLER EVALUATION OF AORTIC VALVE DISEASE
DOPPLER EVALUATION OF RIGHT SIDED LESIONS AND PULMONARY HYPERTENSION
DOPPLER ASSESSMENT OF PROSTHETIC VALVES
DOPPLER ECHOCARDIOGRAPHY IN THE EVALUATION OF CONGENITAL HEART DISEASE
EVALUATION OF CARDIAC FUNCTION AND ASSESSMENT OF CARDIOMYOPATHY BY DOPPLER ECHOCARDIOGRAPHY
SELECTED CASE STUDIES AND DOPPLER COLOR-FLOW MAPPING

The white lie.

"I can handle it."

The facts say otherwise. Cocaine *can't* be handled, by anyone. Neither can crack, or any number of other addictive substances.

But the truth about drug addiction doesn't come easy for people who are constantly lying to themselves. Finding a solution to this devastating problem begins by looking for the problem itself. And very few people are in a better position than you to do the looking. The "white lie" is simply a cover-up for a dark truth: drug abuse kills. Do what you do best: heal.

Looking for drug abuse—make it a habit.

CORONARY ARTERY DISEASE

Effects of Encainide, Flecainide, Imipramine and Moricizine on Ventricular Arrhythmias During the Year After Acute Myocardial Infarction: The CAPS

THE CARDIAC ARRHYTHMIA PILOT STUDY (CAPS) INVESTIGATORS*

The National Heart, Lung, and Blood Institute initiated the Cardiac Arrhythmia Pilot Study (CAPS) to evaluate the feasibility of suppressing ventricular arrhythmias after acute myocardial infarction. Ten centers enrolled 502 patients younger than 75 years of age with ≥10 ventricular premature complexes (VPC) per hour in a 24-hour electrocardiographic recording and a left ventricular ejection fraction >20%. Patients were enrolled 6 to 60 days after acute myocardial infarction and randomized to 1 of 5 treatment tracks with 2 drugs that included encainide, flecainide, imipramine, moricizine or placebo. During a double-blind drug and dose selection phase, investigators were permitted to change drug or dosage to achieve ≥70% suppression in VPC frequency and >90% suppression of runs of VPC with the exception of patients assigned to placebo, who continued receiving it. Patients were followed for a year after randomization. Patients in the 5 treatment arms were similar in age, sex, clinical characteristics, VPC frequency, left ventricular ejection fraction and concomitant drug treatment. As first drugs, encainide and flecainide had higher efficacy rates, 79% and 83%, respectively, than imipramine, 52%, moricizine, 66%, or placebo, 37%. Encainide and flecainide also had high efficacy rates, 68% and 69%, in patients who failed imipramine or moricizine. Encainide, flecainide and moricizine were well tolerated. These 3 drugs had intolerable adverse effect rates of 6% or less, i.e., similar to placebo. More than 70% of the patients who started the follow-up phase on encainide, flecainide or moricizine remained on these drugs to the end of the study. Imipramine had a high intolerable adverse effect rate. The results of CAPS indicate that large-scale clinical trials to evaluate the effect of ventricular arrhythmia suppression with antiarrhythmic drugs on mortality are feasible.

*Members of the Cardiac Arrhythmia Pilot Study (CAPS) are listed in the Appendix.

There is considerable evidence that the presence of ventricular premature complexes (VPCs) predict mortality after acute myocardial infarction (AMI).[1-6] Ruberman[1] showed that complex VPC in a 1-hour electrocardiographic recording identified patients at high risk for both total and sudden cardiac death. Moss et al[2] found that both frequency and complexity of VPC predicted sudden cardiac death and nonsudden cardiac death. Bigger et al[3] showed that ventricular arrhythmias predict mortality independent of left ventricular dysfunction assessed by New York Heart Association class, rales in the coronary care unit and left ventricu-

lar ejection fraction. Similarly, Mukharji et al[4] found that patients with ≥10 VPC/hour had a mortality rate nearly 4 times that of patients with <10 VPC/hour after adjusting for left ventricular ejection fraction.

Given the evidence available, it is reasonable to hope that suppression of ventricular arrhythmias after AMI with antiarrhythmic drugs will improve survival, but there is no significant evidence to support this hypothesis. Furberg[7] summarized the clinical trials in post-AMI patients and emphasized that methodologic problems could account for failure to observe a reduction in mortality with antiarrhythmic therapy. Problems included: (1) inadequate sample size; (2) failure to enroll patients with arrhythmias; (3) failure to assess antiarrhythmic effect; (4) lack of dose titration; and (5) no option to use a second drug if the first failed. Such methodologic problems may have compromised trials with phenytoin, aprindine, mexiletine and tocainide.[8–14]

The National Heart, Lung, and Blood Institute initiated the Cardiac Arrhythmia Pilot Study (CAPS) to obtain knowledge needed for planning a full-scale study to test the hypothesis that long-term suppression of ventricular arrhythmias after AMI with antiarrhythmic drugs will improve survival. Some of the objectives were to: (1) develop methods for identifying and recruiting patients post infarction arrhythmias; (2) develop methods for drug and dose determination in a double-blind clinical trial; (3) determine whether a treatment can suppress VPC rates by at least 70% in about 80% of patients; (4) assess the efficacy and adverse effects of antiarrhythmic drugs over a 1-year period; (5) characterize the natural history of ventricular arrhythmias in the year following AMI; and (6) evaluate the relation between behavioral factors and ventricular arrhythmias after AMI. The present report will provide the results related to the first 4 objectives.

Methods

CAPS was a double-blind, placebo-controlled, randomized trial conducted in 10 clinical centers, a coordinating center, a drug distribution center, a central ambulatory electrocardiogram reading center and the National Heart, Lung, and Blood Institute project office.[15,16] CAPS was divided into 3 phases: (1) patient recruitment; (2) drug and dose selection; and (3) follow-up.

TABLE I Doses of Drugs Used in the Cardiac Arrhythmia Pilot Study

Drug	Total Daily Dose (mg)		
	Low	Medium	High
Encainide	105	150	180
Flecainide	200	300	400
Imipramine	150	225	375
Moricizine	600	750	900

These drugs and a corresponding placebo were donated as follows: encainide by Bristol-Myers Research Laboratories; flecainide by Riker Laboratories; imipramine by Ciba-Geigy; moricizine by DuPont Pharmaceuticals.

Patient recruitment phase: Patients were eligible if they had AMI between 6 and 60 days before enrollment, were <75 years of age and demonstrated either an average of ≥10 VPC/hour or ≥5 episodes of unsustained ventricular tachycardia (3 to 9 consecutive VPCs with a rate of ≥100/min) in a qualifying 24-hour ambulatory electrocardiogram. Patients were excluded if they had a left ventricular ejection fraction ≤20%, contraindications to any of the study medications or ≥10 consecutive VPCs at a rate ≥100/min (disqualifying ventricular tachycardia). Patients with ≥10 consecutive VPCs were excluded because of the concern that their physicians often would want to treat them with conventional antiarrhythmic drugs. If there was inadequate VPC frequency in the first 24-hour ambulatory electrocardiogram, the patient could be screened once more up to 60 days after the AMI.

Drug/dose selection phase: The design of CAPS permitted a comparison of encainide, flecainide, imipramine and moricizine treatment with placebo (Figure 1). After qualifying and giving informed written consent, patients were randomly assigned to 1 of 4 active drugs or to a matching placebo. Three doses of the first drug were permitted (Table I). Dosing continued until efficacy, defined as ≥70% reduction of VPC and >90% reduction in unsustained ventricular tachycardia, was achieved. If efficacy was not achieved or if proarrhythmic effects, disqualifying ventricular tachycardia, conduction abnormalities or other intolerable adverse effects occurred, the patient was switched to a second drug in the treatment arm. Patients who started on a drug with class IC action (i.e., encainide or flecainide) were crossed over to a drug with class IA action (i.e., imipramine or moricizine) and vice versa (Figure 1). Up to 3 doses of the second drug also were permitted. If neither drug in a treatment arm was successful, patients were assigned to the drug that was more efficacious or better tolerated, or both. To detect and manage adverse effects, patients were hospitalized in a monitored setting during the first 48 hours of treatment with the first or second CAPS drug.

Definitions of adverse effects: The CAPS definition of proarrhythmic effect was published previously.[15] It required a 3- to 10-fold increase in VPC frequency and a return to baseline after drug discontinuation. Disqualifying ventricular tachycardia was defined as ≥10 consecutive VPCs at a rate ≥100/min. New or worsening heart failure was defined as hospitalization for heart failure or an increase in diuretic or digitalis dose occurring together with ≥2 signs or symptoms of heart failure, or both. Abnormalities in cardiac impulse formation or conduction were defined as heart rate of ≤30 lasting ≥1 minute, any pause in rhythm ≥3.5 seconds, second-degree Mobitz II atrioventricular block, third-degree atrioventricular block, QRS width ≥0.16 second or a QTc prolongation of ≥50% of the pretreatment control.

Placebo: The placebo comparison group was used to control for variability in VPC frequency during follow-up. Also, the placebo group provided a control for the evaluation of apparent adverse effects of active drugs. The use of placebo was considered ethical be-

cause there is no evidence that suppressing VPC after AMI will reduce the mortality rate. Patients who demonstrated lack of efficacy during treatment with placebo as their first drug were switched to a second placebo (Figure 1).

Follow-up phase: After a drug and dose were selected, patients were followed for 1 year after randomization. Change of study drug or adjustment of dosage was not allowed during the follow-up phase. Patients were evaluated by physical examination and ambulatory 24-hour electrocardiogram at 3, 6, 9 and 12 months. During follow-up, temporary suspension of study medication was allowed for certain surgical procedures and for recurrent myocardial infarction. In the absence of contraindications, the CAPS drug was then restarted. CAPS therapy was discontinued during the follow-up phase because of: (1) disqualifying ventricular tachycardia (≥10 consecutive VPCs); (2) conduction abnormalities; (3) proarrhythmic effect[15]; (4) other intolerable adverse effects; or (5) patient or primary physician decision. Although CAPS was not designed with enough power to assess the potential effect of drug treatment on major clinical events, total and cause-specific mortality and recurrent MI were monitored. After the 12-month evaluation, including a 24-hour continuous electrocardiographic recording, study medication was discontinued. At least 4 days after drug discontinuation, a second 12-month 24-hour electrocardiogram was recorded.

Statistical analysis: The design of CAPS was complex and many comparisons are possible. Because of the selective crossover design, the most valid comparison was by randomization group. However, this comparison obscures differences between drugs. Therefore, the main comparison of efficacy and the assessment of adverse effects of CAPS drugs were made by treatment arm at the end of dose titration on the first drug. Adverse effects during follow-up are presented for actual drug exposure rather than intention to treat because (although the potential for bias exists) it was thought that this was the more conservative and clinically meaningful approach. Comparisons of baseline variables between treatment arms were made by chi-square or analysis of variance, as appropriate. Proportions achieving efficacy or having adverse effects at the end of the drug and dose selection phase were compared by chi-square. Suppression of ventricular arrhythmias during the follow-up phase was evaluated by considering the proportion of patients with an average reduction of VPCs of at least 70% throughout the follow-up year. Percent suppression was computed by dividing the mean hourly VPC rates at the end of dosing, and at 3-, 6-, 9- and 12-month follow-up measures by the mean hourly rates of the baseline and all washout measures (usually the baseline and the 12-month washout). The time to a specific adverse event was analyzed by the method of Kaplan and Meier[17]; comparisons between failure time distributions were made using the log rank statistic.[18]

Results

Clinical characteristics: There were 502 patients enrolled in CAPS. At baseline, there were no overall statistically significant differences among the patients assigned to the 5 treatment arms with respect to age,

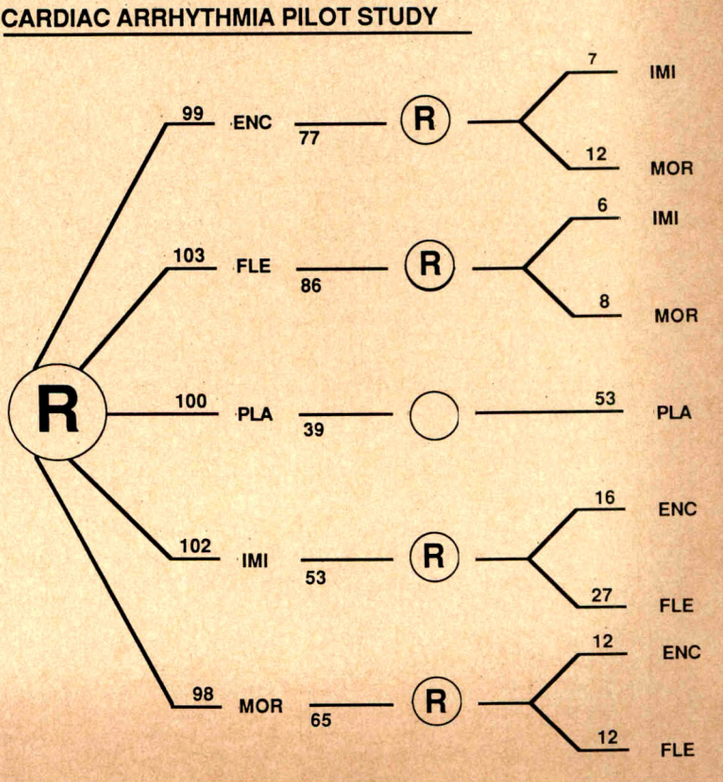

FIGURE 1. Design of the Cardiac Arrhythmia Pilot Study. The *left* column of numbers indicates the number of patients who were randomized to each treatment arm. The *middle* column indicates the number of patients who continued receiving the first drug. The *right* column indicates the number of patients who crossed to a second drug. ENC = encainide; FLE = flecainide; IMI = imipramine; MOR = moricizine; PLA = placebo; R = randomization. For additional information, see Table III.

sex, congestive heart failure, family history of coronary artery disease, smoking, average VPC/hour or ejection fraction (Table II).

Arrhythmia characteristics: All patients had ≥10 VPC/hour in their qualifying Holter recording. In the baseline tape for dosing, an average of 66% of patients (range 53 to 71%) assigned to each treatment arm had ≥30 VPC/hour (Table II); 36% (range 30 to 40%) had 100 VPC/hour or more; and 34% (range 28 to 38%) had 1 or more runs of unsustained ventricular tachycardia (3 to 9 consecutive VPCs).

Results during the drug and dose selection phase: Table III shows the results during the drug and dose selection phase. Two of the 502 patients enrolled withdrew before beginning treatment. During the first step of the drug and dose selection phase, 64% (320 pa-

tients) stayed on the first drug, 4.2% (21 of 500) patients withdrew and 1.2% died (6 of 500). There were 153 patients (31%) in whom CAPS drug 1 lacked efficacy or had intolerable adverse effects. These patients were randomized to CAPS drug 2, with 82% (23 of 28) of them remained on encainide and 85% (33 of 39) flecainide as a second drug, compared to imipramine (23%, 3 of 13) or moricizine (60%, 12 of 20). During dose titration with CAPS drug 2, a total of 112 patients continued receiving drug 2, 16 returned to their first drug, 24 patients withdrew and 1 died. By the completion of the drug and dose selection phase, 89% of the patients (448 of 502) were assigned to a CAPS drug for follow-up: encainide (108), flecainide (119), imipramine (57), moricizine (77) or placebo (87). Patient withdrawal was infrequent during the drug and dose selection phase; only 10.8% of patients either withdrew (9.4%) or died (1.4%).

Time between dose changes: The mean time between dose changes was 11 days during the drug and dose selection phase and was similar for each treatment. The number of days required to complete dosing was shorter for active treatment (encainide 16, flecainide 13, imipramine 20, moricizine 17) than for placebo (32). Patients randomized to placebo required an average of 3.0 dose titration steps compared to 1.7 for active treatment.

Results with CAPS drug 1: Three doses of CAPS drug were permitted and dose titration was continued until efficacy was reached or an adverse effect required switching to another drug in the treatment arm. Table IV describes efficacy and adverse effects of CAPS drug 1 at the completion of dose titration and the reasons for withdrawal during follow-up. Encainide (79%) and flecainide (83%) had higher efficacy rates (>70% VPC and >90% run reduction) than imipramine (52%), moricizine (66%) or placebo (37%) ($p < 0.01$). In addition, encainide, flecainide and moricizine were each more efficacious than placebo ($p < 0.001$). Except for imipramine, efficacy was observed in more patients (76%) with ejection fraction ≥45% than in patients with ejection fraction <45% (64%) ($p < 0.05$). For patients with low left ventricular ejection fraction (<30% or 30 to 44%) moricizine had efficacy rates similar to the drugs with class IC action. At the completion of dose titration on drug 1, there was no significant difference between any of the 5 treatments in the frequency of serious adverse cardiac effects confirmed by drug washout, such as proarrhythmic effect, disqualifying ventricular tachycardia (≥10 consecutive VPCs at a rate of >100/min), conduction abnormalities or heart failure. Imipramine had a 26% incidence of intolerable adverse effects documented by drug washout.

The number of patients who continued receiving the first drug differed: encainide, 85; flecainide, 86; imipramine, 54; moricizine, 65; and placebo, 46. Comparisons of reasons for withdrawal from these groups during follow-up must be viewed cautiously because they no longer contain all of the originally randomized patients. Disqualifying ventricular tachycardia, proarrhythmic effect or syncope that occurred during the follow-up phase, prompted withdrawal from CAPS drug 1 and disappeared during drug washout was seen in 7% of the patients on encainide, 7% on flecainide, 2% on imipramine, 6% on moricizine and 9% on placebo. Death or cardiac arrest occurred during the follow-up phase in 2% of the patients on encainide, 6% on flecainide, 7% on imipramine, 2% on moricizine and 4% on placebo as a first drug. At the end of the study, significantly more patients were taking encainide (64 of 99, 65%) and flecainide (64 of 103, 62%) as first drugs than placebo (35 of 100, 35%).

Results with CAPS drug 2: Findings at the completion of dose titration with CAPS drug 2 were similar to those with CAPS drug 1: encainide (68%) and flecainide (69%) were more effective than imipramine (15%) or moricizine (45%). There were no differences among the CAPS drugs, used as a second drug, in frequency of proarrhythmic effect, disqualifying ventricular tachycardia, conduction abnormalities or heart failure. At the end of the study, the percentage of patients who continued taking CAPS drug 2 were: encainide (20 of 23, 87%); flecainide (25 of 33, 76%); imipramine (2 of 3, 67%) and moricizine (9 of 12, 75%).

Adverse reactions and events in the first 48 hours: Because of concern that serious adverse effects might occur shortly after starting a CAPS drug, patients were hospitalized for at least 48 hours after beginning treatment. There were no differences among treatments with respect to frequency of adverse reactions or events in the first 48 hours (Table V). Serious adverse effects were rare and there were no early deaths that could be ascribed to CAPS treatment. Orthostatic hypotension occurred in 5 patients taking imipramine and was the most frequent early adverse effect.

Adverse effects during the follow-up phase: Reports of moderate to severe adverse effects were analyzed by drug treatment during the follow-up phase

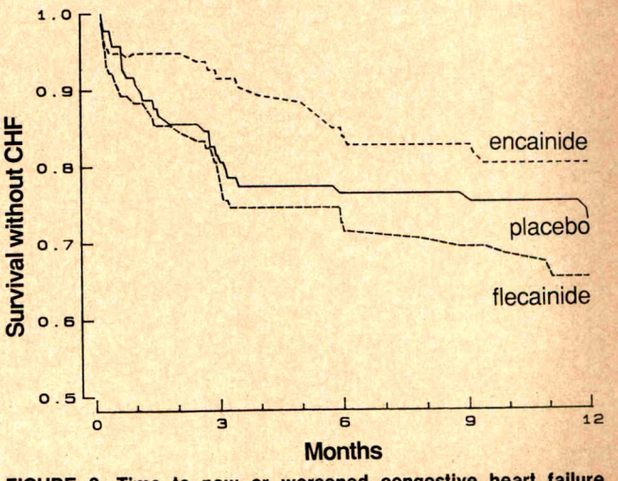

FIGURE 2. Time to new or worsened congestive heart failure (Kaplan-Meier method). Patients randomized to the placebo group, the encainide-imipramine/moricizine treatment arm, or the flecainide-imipramine/moricizine treatment arm are compared. Patients were censored when death or cardiac arrest occurred.

TABLE IV Results of Treatment with First Drug in the CAPS Treatment Arms

	Drug				
	Encainide (n = 99)	Flecainide (n = 103)	Imipramine (n = 102)	Moricizine (n = 98)	Placebo (n = 100)
During the Drug and Dose Selection Phase					
Effective (%)	79	83	52	66	37
LVEF <30%	67	64	47	55	22

Other serious adverse effects	0	1	1	0	0	2
Total	2	2	8	4	5	21

(Table VI). The incidence of any adverse effect was lower for encainide (49%) and flecainide (55%) than for imipramine (67%), moricizine (64%) or placebo (60%). The most common *cardiovascular adverse effect* was dizziness upon standing for moricizine and imipramine (approximately 10%); *gastrointestinal adverse effects* (dry mouth, constipation) were seen most often after imipramine (44%); *genitourinary adverse effects* (decrease in sexual activity, difficulty urinating) occurred most often after encainide, flecainide and moricizine (15 to 18%); *neurologic adverse effects* (poor coordination, clumsiness or stumbling, dizziness or lightheadedness, numbness or tingling) were common for all treatments, including placebo (38%). Imipramine was the only treatment discontinued more frequently (18%) than placebo (7%) because of adverse symptoms (Table VI).

Heart failure: The actuarial 1-year incidence of heart failure was high in CAPS (25%). There was no statistically significant difference between all active treatments and placebo in the incidence of heart failure. In addition, there were no differences between the groups receiving encainide (20%) or flecainide (35%) and the placebo group (27%) (Figure 2).

Compliance: Compliance during the drug and dose selection phase was excellent for each treatment: 90%

TABLE VI Moderate to Severe Adverse Effects Reported Between the End of Drug and Dose Selection Phase and End of Follow-Up Phase (%)*

Category	Drug Assigned at End of Dosing				
	Encainide (n = 108)	Flecainide (n = 119)	Imipramine (n = 57)	Moricizine (n = 77)	Placebo (n = 87)
Cardiovascular	17	19	25	23	21

Any symptom	49	55	67	64	60
Stopped drug because of symptom	2	3	18	6	7

* Only adverse effects reported while taking the drug assigned at the end of the drug and dose selection phase were counted; † burning or prickling of the skin; skin rash; ‡ dry mouth; nausea; vomiting; abdominal pain; diarrhea; constipation; § difficulty urinating; decrease in sexual activity; ‖ poor coordination; dizziness or lightheadedness; numbness or tingling; blurred vision; drowsiness; stuttering; tremor; nightmares; insomnia; ¶ headache; abnormal sense of well being; seeing or hearing things that aren't real; restlessness or nervousness; frequent depression that interferes with work, recreation or sleep; unusual tiredness or fatigue; fever.

had at least 80% compliance at each pill count (range 86 to 96%). During the follow-up phase, at least 80% compliance was noted in 71% taking encainide and 80% taking flecainide.

Mortality: There were no significant differences in mortality rate among the treatments. It was recognized during the design of CAPS that the number of fatal or major arrhythmic events would be insufficient to detect a treatment effect.

Discussion

Ventricular arrhythmias have been identified as an independent risk factor for cardiac mortality following AMI. To test the hypothesis that VPC suppression after AMI improves survival, adequate numbers of patients with significant ventricular arrhythmias will have to be enrolled, randomized to effective and tolerated antiarrhythmic agents or placebo and followed. To date, no large-scale clinical trials to test this hypothesis have been performed.[7] CAPS was undertaken to determine whether it is feasible to carry out such a study. The goals of CAPS were achieved, paving the way for a subsequent large-scale trial to assess effects of VPC suppression on mortality.

Feasibility: The CAPS showed that: (1) it is possible to identify and recruit suitable subjects for a definitive trial; (2) well tolerated, highly efficacious antiarrhythmic agents exist for ventricular arrhythmias after AMI; (3) dose titration with multiple drugs is feasible under clinical trial conditions; and (4) patient compliance and follow-up can be maintained in a postinfarction cohort. CAPS also showed that large numbers of patients must be screened to identify and enroll a sufficient number of qualified postinfarction patients.[16] Nearly 4,000 patients met other eligibility criteria and were screened with a 24-hour electrocardiographic recording to enroll 502 eligible patients. Additionally, CAPS showed that 2 drugs, encainide and flecainide, successfully suppress VPC after AMI, with no more adverse effects than placebo and with excellent compliance. Efficacy rates would have been lower and withdrawal rates higher had CAPS used only 1 dose level of 1 drug.

Drug efficacy and overall adverse effects with placebo: The placebo treatment arm permitted us to observe the natural history of ventricular arrhythmias after AMI. The apparent efficacy of 37% during dose titration with placebo reflected the high degree of spontaneous variability in VPC frequency and more frequent recording in the placebo group. The high frequency of apparent efficacy in this group must be considered in the design and analysis of any large-scale mortality reduction trial. The adverse effects encountered in the placebo treatment arm were compared with the active treatment arms. During treatment with a first drug (Table IV), there was no significant difference between placebo and active drugs in the incidence of conduction abnormalities, congestive heart failure or proarrhythmic effects. Similarly, in both the drug and dose selection and follow-up phases (Tables IV and VI), there was no difference between placebo, encainide, flecainide and moricizine in the incidence of intolerable noncardiac adverse effects.

Drug efficacy and overall adverse effects with active drugs: CAPS drugs with class IC action were more effective in suppressing ventricular arrhythmias than drugs with IA action. In both the drug and dose selection and follow-up phases, the efficacy of encainide and of flecainide was similar and superior to imipramine and moricizine (Table IV). However, the efficacy of moricizine approached that of encainide and flecainide when it was used as the first drug in patients with low left ventricular ejection fraction (<30 or <45%) or

as the second drug. Twelve of 20 patients who took moricizine as a second drug were assigned to it at the start of the follow-up phase (Table III).

The superior efficacy of encainide and flecainide was not associated with a higher frequency of adverse effects. Encainide and flecainide were similar to each other in their adverse effect profile and tended to have fewer adverse effects than imipramine, moricizine or placebo (Tables IV to VI). No drug was different from placebo with respect to heart failure, but flecainide had a slightly higher incidence of moderate to severe heart failure than encainide (Figure 2). Considering the multiple comparisons, the latter difference was not statistically significant. Whether this finding has clinical significance is uncertain. Previous studies have shown that flecainide can aggravate heart failure, particularly in patients in New York Heart Association functional classes III and IV and left ventricular ejection fraction <30%.[19] Overall, fewer than 5% of the patients had to stop the CAPS drug because of heart failure during drug and dose selection or follow-up phases. Other adverse effects tended to occur less frequently on drugs with class IC action than on drugs with class IA action. Thus, encainide and flecainide are not only effective for treating ventricular arrhythmias after AMI but also are safe and well tolerated.

Additional comments: Because of the exclusion criteria used in CAPS, one cannot extrapolate the results to the entire post-AMI population. CAPS excluded patients with ventricular tachycardia ≥10 complexes and left ventricular ejection fraction ≤20%. Aggravation of heart failure or proarrhythmia might occur more frequently in patients with left ventricular ejection fraction ≤20% or sustained ventricular tachycardia, were they exposed to these drugs.[19,20]

CAPS was the first trial to compare encainide and flecainide after AMI. These drugs had high efficacy rates and were well tolerated in the year after infarction. This finding is consistent with previous studies in other populations.[21-24] Currently, the use of antiarrhythmic drugs after AMI in asymptomatic patients is of unproven value. The Cardiac Arrhythmia Suppression Trial is assessing the ability of long-term suppression of ventricular arrhythmias after AMI to reduce the sudden cardiac death rate.

Adoption of Thrombolytic Therapy in the Management of Acute Myocardial Infarction

MARK A. HLATKY, MD, HARRY COTUGNO, PhD, CHRISTOPHER O'CONNOR, MD, DANIEL B. MARK, MD, MPH, DAVID B. PRYOR, MD, and ROBERT M. CALIFF, MD

A national survey of 1,065 physicians was carried out to document current use of thrombolytic therapy for acute myocardial infarction (AMI). In early 1987, thrombolytic therapy was used by 66% of respondents. Among those who used thrombolytic therapy, 92% used streptokinase, 13% used tissue-type plasminogen activator and 3% used urokinase. Most (72%) used intravenous administration exclusively and only 5% used intracoronary administration exclusively. Despite widespread acceptance of thrombolytic therapy, most physicians gave it to <25% of their patients. Duration of symptoms was rated as the single most important factor affecting the decision to use thrombolytic therapy; 45% had a time limit of <4 hours and 85% had a time limit of <6 hours. Complications of AMI and electrocardiographic findings were factors also considered in the decision to give this therapy. A physician's adoption of thrombolytic therapy was significantly associated with several characteristics: specialty type, number of AMI patients treated, physician age and access to cardiac catheterization. In addition, physicians using thrombolytic therapy had a significantly different use of medications and laboratory tests for all patients with AMI. This survey documents rapid acceptance of thrombolytic therapy for AMI, particularly in patients with short duration of symptoms or evidence of high risk.

(Am J Cardiol 1988;61:510–514)

A radical change has occurred over the past decade in the approach to patients with acute myocardial infarction (AMI). In 1980, DeWood et al[1] showed that acute coronary thrombosis can be identified angiographically in most patients with AMI. This observation was quickly followed by a flurry of reports demonstrating that lysis of the coronary thrombus could be achieved by intracoronary infusion of streptokinase.[2–4] Other studies demonstrated the efficacy of intravenous streptokinase[5] and tissue-type plasminogen activator (t-PA) in lysing coronary thrombi,[6,7] and subsequent research suggested that such therapy may salvage myocardium and reduce mortality.[8–11] The impact of thrombolytic therapy upon the care of patients with AMI by practicing physicians remains uncertain. This study documents current patterns of use of thrombolytic therapy for AMI and examines the process by which such therapeutic innovations are adopted into practice.

Methods

The methods of this study have been described in detail elsewhere.[12] Briefly, a self-administered questionnaire regarding management of AMI was prepared that included items concerning thrombolytic therapy as well as items previously used in a 1979 survey of physician practice in the management of uncomplicated AMI.[13] The questionnaire was mailed by the Gallup Organization in January 1987 to cardiologists, internists and family and general practitioners randomly chosen from the American Medical Association's Physician Masterfile. Usable responses were received from 1,065 physicians, 21% of those contacted.

Completed questionnaires were entered into computer storage and checked for accuracy and completeness by the Gallup Organization. Data were subsequently transferred to Duke University Medical Center for analysis using SAS statistical software. Dif-

ferences in discrete valued variables were assessed for statistical significance using chi-square tests and differences in ordered and continuous variables by Wilcoxon rank-sum tests. Multivariable analyses of factors related to the adoption of thrombolytic therapy were performed using multiple logistic regression.

Results

In 1980, only 2% of respondents used thrombolytic therapy to treat patients with AMI, whereas by 1985 their number rose to 50% and by 1987 to 66% (Figure 1A). In early 1987, 92% of physicians administering thrombolytic therapy for AMI used streptokinase, 13% used tissue-type plasminogen activator (t-PA) and 3% used urokinase (these figures total >100% because some physicians used more than 1 agent). Most respondents (72%) used the intravenous route exclusively, 5% used the intracoronary route exclusively, 19% used either route and the remaining 4% did not specify a route of administration.

Respondents rated several factors as either "very important," "somewhat important," "not too important," and "not at all important" in their decision to give a patient thrombolytic therapy (Table I). Duration of pain was the single most important factor in this decision, and 4 to 6 hours was the general time limit beyond which the physician would not give thrombolytic therapy (Figure 2). Ongoing pain was also a key factor in this decision, as were specific complications of AMI such as hypotension and ventricular tachycardia or fibrillation. Electrocardiographic factors such as site of infarction, presence of Q waves and height and extent of ST-segment elevation were considered in the decision to use thrombolytic therapy, but were not of decisive importance. Finally, the patient's age was clearly a factor, whereas the patient's sex was not.

Despite widespread acceptance of thrombolytic therapy for AMI, respondents who used this therapy gave it only to a minority of their patients. Most respondents (58%) used thrombolytic therapy in less than one-quarter of their patients with AMI, 25% used it in one-quarter to one-half, and only 17% used it in more than half of their patients. In order to explore whether stringent patient selection criteria were responsible for the low proportion of AMI patients given thrombolytic therapy, we formed a "selectivity index" by counting the number of factors from Table I that a physician rated as "very important" in the decision to give thrombolytic therapy. There was no significant correlation between a physician's "selectivity index" and the proportion of his patients with AMI given thrombolytic therapy (Spearman correlation coefficient = −0.05, p = 0.22). In contrast, physicians who accepted a longer time interval between onset of symptoms and administration of the thrombolytic agent treated a significantly greater proportion of their AMI patients with thrombolytic therapy (Spearman correlation coefficient = +0.10, p = 0.0085).

Coronary angiography was generally recommended (73%) for patients with uncomplicated AMI given thrombolytic therapy. Very few physicians, however, recommended cardiac catheterization immediately

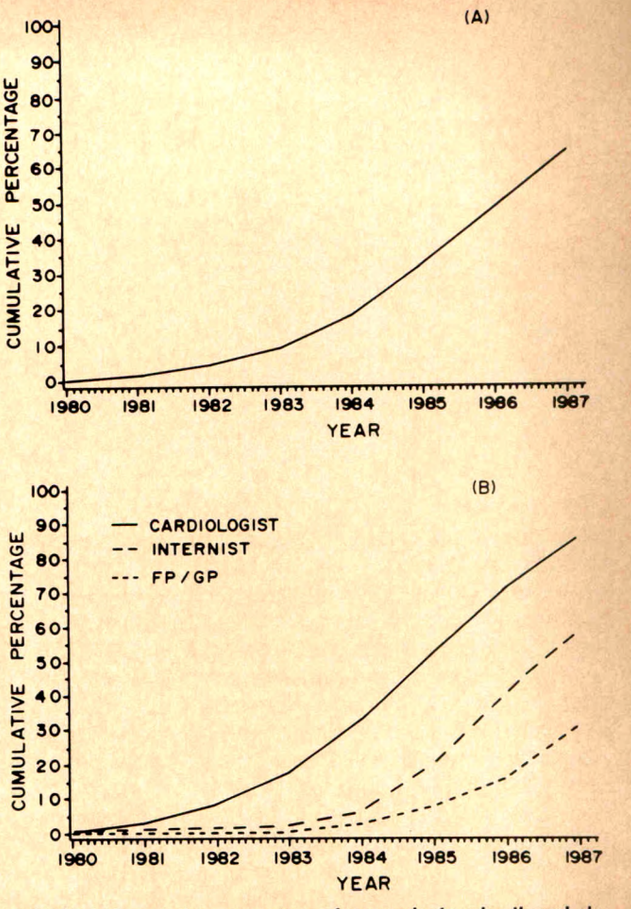

FIGURE 1. Cumulative percentage of respondents using thrombolytic therapy in various calendar years. The top panel shows the data from all respondents (*A*), and the bottom panel shows data according to physician specialty type (*B*). FP/GP = family practice or general practice.

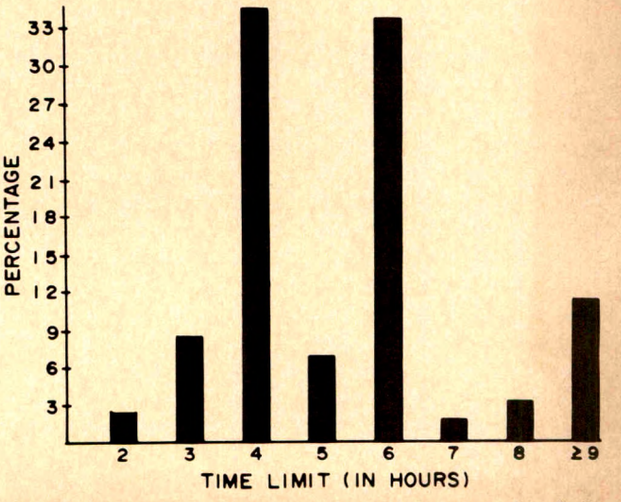

FIGURE 2. Percentage of respondents who set various time limits between the onset of symptoms and administration of thrombolytic therapy.

TABLE I Factors Affecting the Decision to Use Thrombolytic Therapy (n = 1,065)

Factor	Very Important (%)	Somewhat Important (%)	Not Too Important (%)	Not at All Important (%)
Duration of pain	78	16	4	2
Continuing pain	57	30	10	3
Hypotension or shock	53	36	8	3
Age (yrs)	40	45	12	3
VT/VF	33	36	23	8
Anterior vs inferior AMI	28	43	19	10
Presence of Q waves	23	43	23	11
Height of ST elevation	23	35	29	13
Number of leads with ST elevation	20	41	27	12
History of prior AMI	15	44	28	13
Reciprocal ST depression	9	30	41	20
Patient's sex	1	8	30	61

AMI = acute myocardial infarction; VT/VF = ventricular tachycardia or fibrillation.

upon hospital admission. Specifically, only 13% of physicians who used thrombolytic therapy and who had cardiac catheterization facilities in their hospital routinely recommended coronary angiography immediately on admission for patients with AMI.

Therapy acceptance: Thrombolytic therapy was adopted relatively early after its introduction by some physicians, and much later or not at all by others. Several physician characteristics were significantly correlated with the time at which he began to use thrombolytic therapy. Specialty type was the single most important factor (Figure 1B): cardiologists generally adopted thrombolytic therapy. first, followed roughly 2 years later by internists and 2 years after that by family and general practitioners ($p < 0.0001$). Therapy adoption was also significantly affected by physician age, private practice, group practice size, volume of AMI patients and availability of cardiac catheterization (Table II).

Multivariable logistic regression analysis revealed that the independent factors affecting physician acceptance of thrombolytic therapy were specialty ($p < 0.0001$), number of patients with AMI treated in 1986 ($p < 0.0001$), physician age ($p < 0.0001$), and availability of a cardiac catheterization laboratory in the physician's hospital ($p = 0.008$). After accounting for these factors, the size of the physician's practice group and whether the physician was in private practice had no independent effect on the likelihood of using thrombolytic therapy.

Practice style and thrombolytic therapy: In addition to questions about thrombolytic therapy, the survey contained questions about the general manage-

ment of patients with uncomplicated AMI. We examined these responses in detail to determine whether the physicians who used thrombolytic therapy had a distinct practice style with regard to patients with AMI. Physicians who used thrombolytic therapy gave a significantly different set of medications to *all* their patients with AMI (Table III). Physicians who used thrombolytic therapy were more likely to use aspirin routinely in all patients with AMI, both during the initial hospitalization and after discharge. They also were significantly more likely to use β blockers and calcium antagonists and significantly less likely to use digitalis, prophylactic antiarrhythmics and lipid-lowering drugs routinely in patients with AMI.

Physicians using thrombolytic therapy also employed a significantly different predischarge evaluation for *all* their patients with AMI (Table IV). Exercise electrocardiography was recommended by >90% of such physicians and cardiac catheterization also was recommended more frequently, especially in patients with positive exercise tests or non-Q-wave AMIs. Physicians using thrombolytic therapy were more likely to use 24-hour ambulatory monitoring, resting radionuclide angiography and exercise thallium scintigraphy, although these tests were not used routinely by most physicians.

TABLE IV Percentage of Physicians Using Various Predischarge Laboratory Tests, According to Their Use of Thrombolytic Therapy (n = 1,065)

Test	Thrombolytic Therapy User		p Value
	Yes (%)	No (%)	
Exercise electrocardiogram	91	68	<0.0001
Cardiac catheterization for positive exercise electrocardiogram	91	68	<0.0001
Cardiac catheterization for non-Q-wave AMI	79	63	<0.0001
Ambulatory electrocardiogram	44	29	<0.0001
Rest radionuclide angiogram	18	11	0.006
Exercise radionuclide angiogram	8	8	0.89
Exercise thallium scintigram	17	11	0.01

AMI = acute myocardial infarction.

Discussion

This study demonstrates that thrombolytic therapy is now widely accepted in the management of AMI. The most common method of thrombolysis in early 1987 was the administration of intravenous streptokinase, typically in the dose of 1.5 million units. Intracoronary administration of thrombolytic agents was generally not employed in the treatment of AMI, even by physicians with cardiac catheterization facilities available in their hospital. Thus, although intracoronary administration was crucial in gaining acceptance of the thrombolytic therapy for AMI, the advantages of the intravenous route in rapidity and ease of administration have apparently left few using the intracoronary route. Thrombolytic agents other than streptokinase were not frequently used in early 1987, but the results from ongoing trials[7] suggest that tissue-type plasminogen activator (t-PA) use will increase now that this drug has been approved by the Food and Drug Administration.

Physicians considered many factors in their decision to give thrombolytic therapy to a patient with AMI (Table I), the single most important factor being the duration of the patient's symptoms. Most physicians (85%) would not give thrombolytic therapy >6 hours after onset of symptoms (Figure 2). Because the location of the AMI and the presence of complications such as hypotension, shock or ventricular fibrillation were rated as very important factors in the decision to use thrombolytic therapy, the data also suggest that physicians were reserving it for more severely affected patients.

One striking finding was that despite the widespread acceptance of thrombolytic therapy, most physicians gave it to <25% of their patients. Our data suggest that the main reason may be the stringent time limits physicians place on the interval between symptom onset and drug administration. Although physicians clearly considered many factors in the decision to give a patient thrombolytic therapy (Table I), only the time limit a physician placed on the duration of symptoms was significantly correlated with the proportion of patients treated. These findings suggest that most AMI patients will be treated with thrombolytic therapy only if the sources of treatment delay can be identified and eliminated.

Thrombolytic therapy has been adopted primarily by the physicians who treat the most patients with AMI, and by younger physicians. In addition, physicians in the hospitals with facilities to perform cardiac catheterization were more likely to adopt this therapy. Because most physicians do not generally use emergency coronary angiography, this finding may reflect an overall more aggressive approach toward coronary revascularatization in such hospitals.

Physicians who used thrombolytic therapy also appear to have a distinctly different management style for all AMI patients. Specifically, they use β blockers, platelet active drugs such as aspirin and calcium antagonists more frequently (Table III). Furthermore, they were also more likely to use exercise testing and cardiac catheterization in patients with AMI (Table IV), presumably in an attempt to document residual jeopardized myocardium suitable for revascularization procedures. Due to the wording of the questions in this survey, the data in Tables III and IV refer to the physicians' management approach to *all* of their AMI patients, not just to the patients treated with thrombolytic therapy. Thus, the data in Table III indicate that 17% of physicians who use thrombolytic therapy administer intravenous β blockers routinely to all their AMI patients, and *not* that 17% of patients given thrombolytic therapy are given intravenous β blockers. Despite this limitation of the data, it appears that users of thrombolytic therapy have a more aggressive overall approach to the management of AMI patients, including a more extensive use of both medications and laboratory testing.

This study had a number of other important limitations. First, it was a survey of how physicians say they practice, rather than an actual audit of their practices. Second, many physicians did not participate in the study. Because nonrespondents may differ from respondents in a variety of ways, our results must be interpreted with caution. In particular, although a stratified random sample of physicians across the U.S. was used in this survey, the possibility of nonresponse bias must be considered in any extrapolation of these results to national estimates.

ZEST...!

In ACE inhibition

24-hour power with one tablet a day

New

ZESTRIL®!

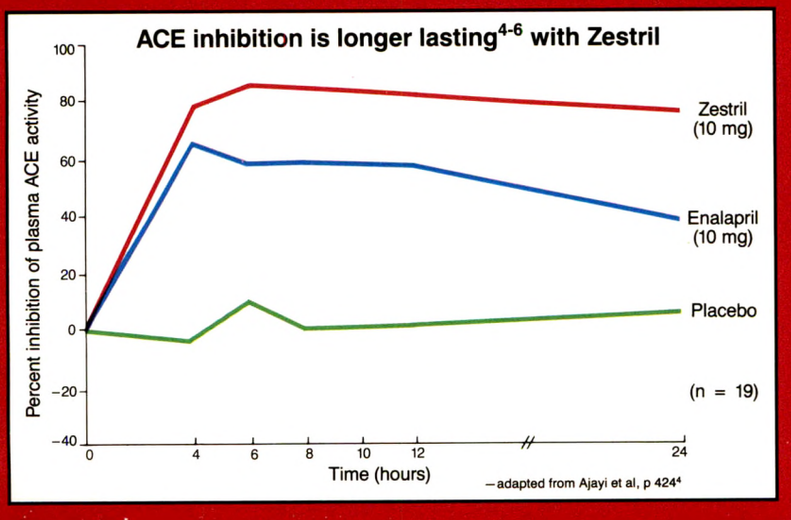
LISINOPRIL

STUART

STUART PHARMACEUTICALS
Division of ICI Americas Inc.
Wilmington, Delaware 19897

Zestril: The longest-acting ACE inhibitor for treating hypertension

Zestril assures 24-hour blood pressure control with a half-life of almost 13 hours.[1] That's longer than that of either enalapril[2] or captopril.[3] So angiotensin converting enzyme (ACE) inhibition with Zestril is longer lasting than enalapril—sustained 24 hours after a single dose.[4-6]



Zestril: Hypertensive patients start and stay at one tablet a day

A single tablet of Zestril controls blood pressure for a full 24 hours[7]—unlike other ACE inhibitors, which may have to be increased to b.i.d.[2] or t.i.d.[3] dosing in some patients. The predictable once-daily dosage of Zestril enhances patient compliance and cost effectiveness.

Zestril: 24-hour blood pressure control without reliance on metabolism

Zestril provides complete 24-hour control without reliance on liver metabolism.[8] It does not require bioactivation[8]—as needed with the prodrug enalapril.[2,8] Absorption is unaffected by food.[9]

Zestril: 24-hour blood pressure control that's well tolerated

Zestril achieves 24-hour control with a low incidence of side effects. It is a nonsulfhydryl-containing drug. That's why rash and/or taste disturbance sometimes associated with the sulfhydryl-containing drug captopril[10] are rarely seen with Zestril. In Zestril clinical trials, the most frequently reported side effects were as follows:

Side Effects	Zestril (n = 2,003*)	—	Placebo (n = 207)
Dizziness	6.3%	—	1.9%
Headache	5.3%	—	1.9%
Fatigue	3.3%	—	1.0%
Diarrhea	3.2%	—	2.4%
Upper respiratory symptoms	3.0%	—	0.0%
Cough	2.9%	—	1.0%

*Includes 420 patients treated for congestive heart failure who were receiving concomitant digitalis and/or diuretic therapy.

- Only 6% of patients discontinued therapy in controlled clinical trials.
- Symptomatic hypotension occurs infrequently (0.8%) in patients with normal renal function.

Zestril dosage in hypertension
Starting dose is 10 mg once a day. Usual dosage range for maintenance: 20 to 40 mg per day, administered in a single daily dose.

ZESTRIL®!
LISINOPRIL STUART

Please see last page of this advertisement for brief summary of prescribing information.

INDICATIONS AND USAGE. Zestril is indicated for the treatment of hypertension. It may be used alone as initial therapy or concomitantly with other classes of antihypertensive agents. In using Zestril, consideration should be given to the fact that another angiotensin converting enzyme inhibitor, captopril, has caused agranulocytosis, particularly in patients with renal impairment or collagen vascular disease, and that available data are insufficient to show that Zestril does not have a similar risk. (See WARNINGS.) **CONTRAINDICATIONS.** Zestril is contraindicated in patients who are hypersensitive to this product. **WARNINGS. Angioedema:** Angioedema of the face, extremities, lips, tongue, glottis and/or larynx has been reported in patients treated with angiotensin converting enzyme inhibitors, including Zestril. In such cases, Zestril should be promptly discontinued, and the patient carefully observed until the swelling disappears. In instances where swelling has been confined to the face and lips the condition has generally resolved without treatment, although antihistamines have been useful in relieving symptoms. Angioedema associated with laryngeal edema may be fatal. **Where there is involvement of the tongue, glottis or larynx, likely to cause airway obstruction, appropriate therapy, eg, subcutaneous epinephrine solution 1:1000 (0.3 mL to 0.5 mL) should be promptly administered. (See ADVERSE REACTIONS.) Hypotension:** Excessive hypotension was rarely seen in uncomplicated hypertensive patients but is a possible consequence of use with Zestril in salt/volume-depleted persons, such as those treated vigorously with diuretics or patients on dialysis. (See PRECAUTIONS, Drug Interactions and ADVERSE REACTIONS.) In patients with severe congestive heart failure, with or without associated renal insufficiency, excessive hypotension has been observed and may be associated with oliguria and/or progressive azotemia, and rarely with acute renal failure and/or death. Because of the potential fall in blood pressure in these patients, therapy should be started under very close medical supervision. Such patients should be followed closely for the first two weeks of treatment and whenever the dose of Zestril and/or diuretic is increased. Similar considerations apply to patients with ischemic heart or cerebrovascular disease in whom an excessive fall in blood pressure could result in a myocardial infarction or cerebrovascular accident. If hypotension occurs, the patient should be placed in supine position and, if necessary, receive an intravenous infusion of normal saline. A transient hypotensive response is not a contraindication to further doses which usually can be given without difficulty once the blood pressure has increased after volume expansion. **Neutropenia/Agranulocytosis:** Another angiotensin converting enzyme inhibitor, captopril, has been shown to cause agranulocytosis and bone marrow depression, rarely in uncomplicated patients but more frequently in patients with renal impairment especially if they also have a collagen vascular disease. Available data from clinical trials of Zestril are insufficient to show that Zestril does not cause agranulocytosis at similar rates. Periodic monitoring of white blood cell counts in patients with collagen vascular disease and renal disease should be considered. **PRECAUTIONS. General. Impaired Renal Function:** As a consequence of inhibiting the renin-angiotensin-aldosterone system, changes in renal function may be anticipated in susceptible individuals. In patients with severe congestive heart failure whose renal function may depend on the activity of the renin-angiotensin-aldosterone system, treatment with angiotensin converting enzyme inhibitors, including Zestril, may be associated with oliguria and/or progressive azotemia and rarely with acute renal failure and/or death. In hypertensive patients with unilateral or bilateral renal artery stenosis, increases in blood urea nitrogen and serum creatinine may occur. Experience with another angiotensin converting enzyme inhibitor suggests that these increases are usually reversible upon discontinuation of Zestril and/or diuretic therapy. In such patients, renal function should be monitored during the first few weeks of therapy. Some hypertensive patients with no apparent pre-existing renal vascular disease have developed increases in blood urea nitrogen and serum creatinine, usually minor and transient, especially when Zestril has been given concomitantly with a diuretic. This is more likely to occur in patients with pre-existing renal impairment. Dosage reduction of Zestril and/or discontinuation of the diuretic may be required. **Evaluation of the hypertensive patient should always include assessment of renal function. (See DOSAGE AND ADMINISTRATION.) Hyperkalemia:** In clinical trials hyperkalemia (serum potassium greater than 5.7 mEq/L) occurred in approximately 2.2% of hypertensive patients and 4.0% of patients with congestive heart failure. In most cases these were isolated values which resolved despite continued therapy. Hyperkalemia was a cause of discontinuation of therapy in approximately 0.1% of hypertensive patients. Risk factors for the development of hyperkalemia include renal insufficiency, diabetes mellitus, and the concomitant use of potassium-sparing diuretics, potassium supplements and/or potassium-containing salt substitutes, which should be used cautiously, if at all, with Zestril. (See Drug Interactions.) **Surgery/Anesthesia:** In patients undergoing major surgery or during anesthesia with agents that produce hypotension, Zestril may block angiotensin II formation secondary to compensatory renin release. If hypotension occurs and is considered to be due to this mechanism, it can be corrected by volume expansion. **Information for Patients. Angioedema:** Angioedema, including laryngeal edema, may occur especially following the first dose of Zestril. Patients should be so advised and told to report immediately any signs or symptoms suggesting angioedema (swelling of face, extremities, eyes, lips, tongue, difficulty in swallowing or breathing) and to take no more drug until they have consulted with the prescribing physician. **Symptomatic Hypotension:** Patients should be cautioned to report lightheadedness especially during the first few days of therapy. If actual syncope occurs, the patient should be told to discontinue the drug until they have consulted with the prescribing physician. All patients should be cautioned that excessive perspiration and dehydration may lead to an excessive fall in blood pressure because of reduction in fluid volume. Other causes of volume depletion such as vomiting or diarrhea may also lead to a fall in blood pressure; patients should be advised to consult with their physician. **Hyperkalemia:** Patients should be told not to use salt substitutes containing potassium without consulting their physician. **Neutropenia:** Patients should be told to report promptly any indication of infection (eg, sore throat, fever) which may be a sign of neutropenia. **NOTE:** As with many other drugs, certain advice to patients being treated with Zestril is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects. **Drug Interactions. Hypotension – Patients on Diuretic Therapy:** Patients on diuretics and especially those in whom diuretic therapy was recently instituted, may occasionally experience an excessive reduction of blood pressure after initiation of therapy with Zestril. The possibility of hypotensive effects with Zestril can be minimized by either discontinuing the diuretic or increasing the salt intake prior to initiation of treatment with Zestril. If it is necessary to continue the diuretic, initiate therapy with Zestril at a dose of 5 mg daily, and provide medical supervision after the initial dose for at least two hours and until blood pressure has stabilized for at least an additional hour. (See WARNINGS, and DOSAGE AND ADMINISTRATION.) When a diuretic is added to the therapy of a patient receiving Zestril, an additional antihypertensive effect is usually observed. Studies with ACE inhibitors in combination with diuretics indicate that the dose of the ACE inhibitor can be reduced when it is given with a diuretic. (See DOSAGE AND ADMINISTRATION.) **Indomethacin:** In a study in 36 patients with mild to moderate hypertension where the antihypertensive effects of Zestril alone were compared to Zestril given concomitantly with indomethacin, the use of indomethacin was associated with a reduced effect, although the difference between the two regimens was not significant. **Other Agents:** Zestril has been used concomitantly with nitrates and/or digoxin without evidence of clinically significant adverse interactions. No clinically important pharmacokinetic interactions occurred when Zestril was used concomitantly with propranolol or hydrochlorothiazide. The presence of food in the stomach does not alter the bioavailability of Zestril. **Agents Increasing Serum Potassium:** Zestril attenuates potassium loss caused by thiazide-type diuretics. Use of Zestril with potassium-sparing diuretics (eg, spironolactone, triamterene or amiloride), potassium supplements, or potassium-containing salt substitutes may lead to significant increases in serum potassium. Therefore, if concomitant use of these agents is indicated because of demonstrated hypokalemia, they should be used with caution and with frequent monitoring of serum potassium. **Carcinogenesis, Mutagenesis, Impairment of Fertility.** There was no evidence of a tumorigenic effect when lisinopril was administered for 105 weeks to male and female rats at doses up to 90 mg/kg/day (about 56 times* the maximum recommended daily human dose) or when lisinopril was administered for 92 weeks to (male and female) mice at doses up to 135 mg/kg/day (about 84 times* the maximum recommended daily human dose). *Based on patient weight of 50 Kg. Lisinopril was not mutagenic in the Ames microbial mutagen test with or without metabolic activation. It was also negative in a forward mutation assay using Chinese hamster lung cells. Lisinopril did not produce single strand DNA breaks in an in vitro alkaline elution rat hepatocyte assay. In addition, lisinopril did not produce increases in chromosomal aberrations in an in vitro test in Chinese hamster ovary cells or in an in vivo study in mouse bone marrow. There were no adverse effects on reproductive performance in male and female rats treated with up to 300 mg/kg/day of lisinopril. **Pregnancy. Pregnancy Category C:** Lisinopril was not teratogenic in mice treated on days 6-15 of gestation with up to 1,000 mg/kg/day (625 times the maximum recommended human dose). There was an increase in fetal resorptions at doses down to 100 mg/kg; at doses of 1,000 mg/kg this was prevented by saline supplementation. There was no fetotoxicity or teratogenicity in rats treated with up to 300 mg/kg/day (188 times the maximum recommended dose) of lisinopril at days 6-17 of gestation. In rats receiving lisinopril from day 15 of gestation through day 21 postpartum, there was an increased incidence in pup deaths on days 2-7 postpartum and a lower average body weight of pups on day 21 postpartum. The increase in pup deaths and decrease in pup weight did not occur with maternal saline supplementation. Lisinopril, at doses up to 1 mg/kg/day, was not teratogenic when given throughout the organogenic period in saline supplemented rabbits. Saline supplementation (physiologic saline in place of tap water) was used to eliminate maternotoxic effects and enable evaluation of the teratogenic potential at the highest possible dosage level. The rabbit has been shown to be extremely sensitive to angiotensin converting enzyme inhibitors (captopril and enalapril) with maternal and fetotoxic effects apparent at or below the recommended therapeutic dosage levels in man. Fetotoxicity was demonstrated in rabbits by an increased incidence of fetal resorptions at a dose of lisinopril at 1 mg/kg/day and by an increased incidence of incomplete ossification at the lowest dose tested (0.1 mg/kg/day). By whole body autoradiography, radioactivity was found in the placenta following administration of labeled lisinopril to pregnant rats, but none was found in the fetuses. There are no adequate and well-controlled studies in pregnant women. Zestril should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. **Nursing Mothers:** Milk of lactating rats contains radioactivity following administration of ^{14}C lisinopril. It is not known whether this drug is excreted in human milk.

ZESTRIL® (lisinopril)

Because many drugs are excreted in human milk, caution should be exercised when Zestril is given to a nursing mother. **Pediatric Use:** Safety and effectiveness in children have not been established. **ADVERSE REACTIONS.** Zestril has been found to be generally well tolerated in controlled clinical trials involving 2003 patients and subjects. The most frequent clinical adverse experiences in controlled trials were dizziness (6.3%), headache (5.3%), fatigue (3.3%), diarrhea (3.2%), upper respiratory symptoms (3.0%), and cough (2.9%), all of which were more frequent than in placebo-treated patients. For the most part, adverse experiences were mild and transient in nature. Discontinuation of therapy was required in 6.0% of patients. In clinical trials, the overall frequency of adverse experiences could not be related to total daily dosage within the recommended therapeutic dosage range. For adverse experiences which occurred in more than 1% of patients and subjects treated with Zestril or Zestril plus hydrochlorothiazide in controlled clinical trials, comparative incidence data are listed in the table below.

Percent of Patients in Controlled Studies

	Zestril (n = 2003†) Incidence (discontinuation)	Zestril/Hydrochlorothiazide (n = 644) Incidence (discontinuation)	Placebo (n = 207) Incidence
Dizziness	6.3 (0.6)	9.0 (0.9)	1.9
Headache	5.3 (0.2)	4.3 (0.5)	1.9
Fatigue	3.3 (0.2)	3.9 (0.5)	1.0
Diarrhea	3.2 (0.3)	2.6 (0.3)	2.4
Upper Respiratory Symptoms	3.0 (0.0)	4.5 (0.0)	0.0
Cough	2.9 (0.4)	4.5 (0.8)	1.0
Nausea	2.3 (0.3)	2.5 (0.2)	2.4
Hypotension	1.8 (0.8)	1.6 (0.5)	0.5
Rash	1.5 (0.4)	1.6 (0.2)	0.5
Orthostatic Effects	1.4 (0.0)	3.4 (0.2)	1.0
Asthenia	1.3 (0.4)	2.0 (0.2)	1.0
Chest Pain	1.3 (0.1)	1.2 (0.2)	1.4

Vertigo	0.1 (0.0)	1.1 (0.2)	0.0

†Includes 420 patients treated for congestive heart failure who were receiving concomitant digitalis and/or diuretic therapy.

Clinical adverse experiences occurring in 0.3% to 1.0% of patients in the controlled trials and rarer, serious, possibly drug related events reported in uncontrolled studies or marketing experience included: BODY AS A WHOLE: Chest discomfort, fever, flushing. CARDIOVASCULAR: Angina pectoris, orthostatic hypotension, rhythm disturbances, tachycardia, peripheral edema, palpitation. DIGESTIVE: Abdominal pain, anorexia, constipation, flatulence. METABOLISM: Gout. MUSCULOSKELETAL: Joint pain, shoulder pain. NERVOUS SYSTEM/PSYCHIATRIC: Depression, somnolence, insomnia, stroke. RESPIRATORY SYSTEM: Bronchitis, sinusitis, pharyngeal pain. UROGENITAL: Oliguria, progressive azotemia, acute renal failure. OTHER: Blurred vision, pruritus, urinary tract infection, vasculitis of the legs. ANGIOEDEMA: Angioedema has been reported in patients receiving Zestril (0.1%). Angioedema associated with laryngeal edema may be fatal. If angioedema of the face, extremities, lips, tongue, glottis and/or larynx occurs, treatment with Zestril should be discontinued and appropriate therapy instituted immediately. (See WARNINGS.) HYPOTENSION: In hypertensive patients, hypotension occurred in 1.2% and syncope occurred in 0.1% of patients. Hypotension or syncope was a cause of discontinuation of therapy in 0.5% of hypertensive patients. (See WARNINGS.) In patients with congestive heart failure, hypotension occurred in 5.0% and syncope occurred in 1.0% of patients. These adverse experiences were causes for discontinuation of therapy in 1.3% of these patients. **Clinical Laboratory Test Findings. Serum Electrolytes:** Hyperkalemia (See PRECAUTIONS.) **Creatinine, Blood Urea Nitrogen:** Minor increases in blood urea nitrogen and serum creatinine, reversible upon discontinuation of therapy, were observed in about 2.0% of patients with essential hypertension treated with Zestril alone. Increases were more common in patients receiving concomitant diuretics and in patients with renal artery stenosis. (See PRECAUTIONS.) Reversible minor increases in blood urea nitrogen and serum creatinine were observed in approximately 9.1% of patients with congestive heart failure on concomitant diuretic therapy. Frequently, these abnormalities resolved when the dosage of the diuretic was decreased. **Hemoglobin and Hematocrit:** Small decreases in hemoglobin and hematocrit (mean decreases of approximately 0.4 g% and 1.3 vol%, respectively) occurred frequently in patients treated with Zestril but were rarely of clinical importance in patients without some other cause of anemia. In clinical trials, less than 0.1% of patients discontinued therapy due to anemia. **Other (Causal Relationship Unknown):** Rarely, elevations of liver enzymes and/or serum bilirubin have occurred. Overall, 2.0% of patients discontinued therapy due to laboratory adverse experiences, principally elevations in blood urea nitrogen (0.6%), serum creatinine (0.5%), and serum potassium (0.4%). **OVERDOSAGE.** The oral LD_{50} of lisinopril is greater than 20 g/kg in mice and rats. The most likely manifestation of overdosage would be hypotension, for which the usual treatment would be intravenous infusion of normal saline solution. **DOSAGE AND ADMINISTRATION. Initial Therapy:** In patients with uncomplicated essential hypertension not on diuretic therapy, the recommended initial dose is 10 mg once a day. Dosage should be adjusted according to blood pressure response. The usual dosage range is 20-40 mg per day administered in a single daily dose. The antihypertensive effect may diminish toward the end of the dosing interval regardless of the administered dose, but most commonly with a dose of 10 mg daily. This can be evaluated by measuring blood pressure just prior to dosing to determine whether satisfactory control is being maintained for 24 hours. If it is not, an increase in dose should be considered. Doses up to 80 mg have been used but do not appear to give greater effect. If blood pressure is not controlled with Zestril alone, a low dose of a diuretic may be added. Hydrochlorothiazide, 12.5 mg has been shown to provide an additive effect. After the addition of a diuretic, it may be possible to reduce the dose of Zestril. **Diuretic Treated Patients:** In hypertensive patients who are currently being treated with a diuretic, symptomatic hypotension may occur occasionally following the initial dose of Zestril. The diuretic should be discontinued, if possible, for two or three days before beginning therapy with Zestril to reduce the likelihood of hypotension. (See WARNINGS.) The dosage of Zestril should be adjusted according to blood pressure response. If the patient's blood pressure is not controlled with Zestril alone, diuretic therapy may be resumed as described above. If the diuretic cannot be discontinued, an initial dose of 5 mg should be used under medical supervision for at least two hours and until blood pressure has stabilized for at least an additional hour. (See WARNINGS and PRECAUTIONS, Drug Interactions.) Concomitant administration of Zestril with potassium supplements, potassium salt substitutes, or potassium-sparing diuretics may lead to increases of serum potassium. (See PRECAUTIONS.) **Use in Elderly:** In general, blood pressure response and adverse experiences were similar in younger and older patients given similar doses of Zestril. Pharmacokinetic studies, however, indicate that maximum blood levels and area under the plasma concentration time curve (AUC) are doubled in older patients so that dosage adjustments should be made with particular caution. **Dosage Adjustment in Renal Impairment:** The usual dose of Zestril (10 mg) is recommended for patients with creatinine clearance > 30 mL/min (serum creatinine of up to approximately 3 mg/dL). For patients with creatinine clearance > 10 mL/min ≤ 30 mL/min (serum creatinine ≥ 3 mg/dL), the first dose is 5 mg once daily. For patients with creatinine clearance < 10 mL/min (usually on hemodialysis) the recommended initial dose is 2.5 mg. The dosage may be titrated upward until blood pressure is controlled or to a maximum of 40 mg daily.

Renal Status	Creatinine-Clearance mL/min	Initial Dose mg/day
Normal Renal Function to Mild Impairment	>30	10
Moderate to Severe Impairment	≥10 ≤30	5
Dialysis Patients	<10	2.5‡

‡Dosage or dosing interval should be adjusted depending on the blood pressure response. Rev E 12/87

Trends in Physician Management of Uncomplicated Acute Myocardial Infarction, 1970 to 1987

MARK A. HLATKY, MD, HARRY E. COTUGNO, PhD, DANIEL B. MARK, MD, MPH, CHRISTOPHER O'CONNOR, MD, ROBERT M. CALIFF, MD, and DAVID B. PRYOR, MD

To document current management of uncomplicated acute myocardial infarction (AMI), a national survey of 1,065 physicians was performed. Items from previous surveys in 1970 and 1979 were included to permit analysis of time trends in management. Median hospital stay dropped from 21 days in 1970 to 9 days in 1987. Use of β blockers and aspirin doubled between 1979 and 1987, while use of anticoagulation and sulfinpyrazone dropped 4- to 10-fold. In 1987, coronary angiography was used commonly, especially in younger patients or those with either a non-Q-wave AMI, intravenous thrombolytic therapy or a positive exercise test. These findings document the increasingly aggressive approach to the management of patients with uncomplicated AMI.

(Am J Cardiol 1988;61:515–518)

Acute myocardial infarction (AMI) is a common and serious illness that accounts for 500,000 deaths annually in the U.S. Management of AMI thus represents an important aspect of medical practice with far-reaching implications in terms of both lives and dollars.

Physician practice in treating uncomplicated AMI was surveyed in 1970 and again in 1979 under the auspices of the American Heart Association.[1,2] Comparison of the results of these 2 surveys documented considerable evolution in the management approach toward AMI between 1970 and 1979. Further advances have been made since the 1979 survey in evaluation and therapy of the AMI patient, but the extent to which these advances in knowledge have been incorporated into practice is uncertain. This study assesses quantitatively current physician practice in the management of AMI and documents the acceptance of new strategies for the evaluation and treatment of AMI.

Methods

A self-administered questionnaire was prepared that included items previously used in the 1979 survey,[2] as well as new items that reflected recent developments in management of AMI. The survey instrument was then pre-tested by the Gallup Organization in a sample of 100 physicians, and revised for clarity and ease of administration.

Questionnaires were mailed in January 1987 to 1,700 cardiologists, 1,700 internists, and 1,700 family and general practitioners randomly chosen from the American Medical Association's Physician Masterfile. A follow-up mailing was sent to all nonrespondents in February 1987, and a third mailing was sent to nonresponding cardiologists in March 1987. A total of 267 questionnaires were undeliverable because the physician had moved, 32 were returned by physicians who had retired from practice, 14 were returned blank and 17 were not usable. Usable responses were received from 1,065 physicians (21%). When telephone follow-up to 100 nonrespondents inquired about the reasons for not participating, most indicated they were too busy or had no interest in responding to surveys.

Completed questionnaires were entered into computer storage and checked for accuracy and completeness by the Gallup Organization. Data were subsequently transferred to Duke University Medical Center for analysis using SAS statistical software.

Results

A total of 1,065 responses were received: 526 from cardiologists, 273 from internists and 266 from family and general practitioners. The majority of respondents

were in private community practice (62%), with the remainder in academic practice (12%), full-time hospital-based practices (9%), health maintenance organizations (3%), fellowship training (2%), with miscellaneous or unavailable practice setting data for the remaining respondents (12%). Half of the respondents graduated from medical school before 1975 and 42% of the respondents had managed 25 or more patients with AMI in the previous year.

As in the 1979 survey, "uncomplicated AMI" was defined in the cover letter as "without serious or recurrent arhythmia, persistent pain, shock, or congestive heart failure." The length of stay for patients with uncomplicated AMI decreased dramatically from 1970 to 1979, and again from 1979 to 1987. The median total hospital stay was 21 days in 1970, 14 days in 1979, and 9 days in 1987. The intensive care unit component of the hospital stay also decreased sharply: 4.5 days in 1970, 3.5 days in 1979, and 2.8 days in 1987.

Physicians were asked to define the drugs they usually prescribed during the hospital stay of patients with uncomplicated AMI and responses were contrasted with those obtained in 1970 and 1979 (Table I). Full-dose anticoagulation with intravenous heparin followed by oral warfarin decreased progressively from 1970 to 1987. Use of prophylactic antiarrhythmics increased from 1970 to 1979, but changed little from 1979 to 1987, with less than half of physicians using them routinely. β-blocker use during hospitalization increased markedly from 1979 to 1987, with 73% of respondents recommending oral agents and 14% using intravenous therapy. Calcium antagonists were not generally available in 1979, but by 1987 were widely used as part of the routine regimen for patients with AMI. In-hospital use of antiplatelet therapy was not

assessed in previous surveys, but in 1987 aspirin was used during hospitalization by over half the physicians and dipyridamole by 20%.

Trends in the predischarge evaluation of the patient with uncomplicated AMI are also summarized in Table I. A lipid panel and an exercise electrocardiogram were obtained by most physicians surveyed, while other predischarge tests were used much more selectively. Exercise test use has increased slightly since the 1979 survey and in 1987 was recommended for most patients with uncomplicated AMI. The use of 24-hour ambulatory electrocardiograms, however, changed little between 1979 and 1987, with the test used routinely by 39% of physicians surveyed. Radionuclide studies were seldom used routinely and have shown little change from 1979 to 1987; the exercise thallium scintigraphy in 1987 was used routinely by 15% of respondents, resting radionuclide ventriculography by 15%, and exercise radionuclide ventriculography by 8%.

The use of coronary angiography for patients with uncomplicated AMI was explored in some detail in the 1987 survey (Table II). When coronary angiography was used, it was generally recommended within 1 to 8 weeks after AMI, rather than in the early phases of infarction. In general, coronary angiography was more often recommended after non-Q-wave AMI than after Q-wave AMI and more often after anterior AMI than after inferior AMI (Table II). Angiography was recommended significantly more often for younger than for older patients. Furthermore, the percentage of younger patients recommended for angiography was much higher than in 1979, when roughly 50% of cardiologists and roughly 33% of internists and 33% of family and general practitioners recommended this procedure for patients younger than 45, whereas in the 1987 survey these figures had risen to 86%, 84% and 72%, respectively. Coronary angiography was usually recommended if the AMI had been treated with intravenous thrombolytic therapy or if there was evidence of residual ischemia on exercise testing.

The drugs usually prescribed for patients with uncomplicated AMI after hospital discharge are summarized in Table III. Data from the current survey are only compared with data from the 1979 survey, because 1970 data were not available. Advice to stop smoking has remained virtually universal and there has been a slight increase in the recommendation for a cholesterol-lowering diet between the 1979 and 1987 surveys. Routine use of β blockers, aspirin and dipyridamole after hospital discharge has essentially doubled between 1979 and 1987, with current β blocker and aspirin use at over 80% and dipyridamole at 25%. In contrast, routine use of sulfinpyrazone (Anturane) has dropped over 10-fold, and routine use of digitalis and anticoagulants has dropped 3-fold to 5-fold since 1979.

The patterns of β-blocker and aspirin use were examined in some detail in the current survey. Almost all respondents (over 80%) prescribed β blockers and aspirin to most patients after uncomplicated AMI in 1987. Of physicians who prescribe β blockers after myocardial infarction, in 1987 48% prescribed them indefinitely, 16% prescribed them for 2 to 3 years, 21% for 1 year and 10% for 6 months. Physicians who prescribed aspirin used relatively low doses: 40% used <325 mg/day, 42% used 325 mg/day and only 2% used >650 mg/day. Roughly 40% of cardiologists and a third of all respondents used enteric, safety-coated aspirin for most patients after uncomplicated AMI.

Physicians in 1987 allowed patients to resume usual activities even earlier after hospital discharge than they did in 1979 and 1970. Activities of relatively low metabolic cost, such as housework or a desk job, were permitted at a median of 6 weeks after uncomplicated AMI in 1987, compared with 8.5 weeks in 1970, and 6.5 to 7 weeks in 1979. Activities of higher metabolic cost, such as heavy labor or working in extremes of heat and cold, were in 1987 permitted at a median of 8 to 10 weeks, respectively, down from 13 to 17 weeks in 1970, and 12 to 13 weeks in 1979.

Discussion

This survey documents dramatic changes in physician management of uncomplicated AMI during the period 1970–1987. Patients are kept in intensive care and in the hospital roughly half as long and permitted to return to activities much sooner after hospital discharge. At the same time, the use of predischarge laboratory studies is much greater and drug treatment is much more aggressive.

Decades ago, long periods of bed rest were recommended for patients with AMI. The value of early mobilization was recognized in the 1940s and became commonly practiced in the 1950s,[3] with the feasibility of early hospital discharge demonstrated in the late 1960s and early 1970s.[4,5] As a result of these studies, the average patient with AMI in early 1987 was kept in the hospital for 9 days: a remarkable reduction from the average length of stay of 21 days in 1970. Further reductions in length of stay are under study, particularly for patients treated with thrombolytic therapy and immediate angioplasty.[6]

In-hospital regimens for the patient with AMI have also evolved considerably. The most dramatic change, the institution of thrombolytic therapy, is discussed in detail in a separate report.[7] β blockers have been used as secondary preventive measures and to reduce infarct size in the acute setting. Although most physicians begin oral β blockade in the hospital, only 14% use intravenous β-blocker therapy in the early stages of AMI. Despite the evidence from randomized studies suggesting a benefit of early intravenous therapy,[8] it appears that the intravenous use of β blockers in the acute phases remains less well accepted than the use of these agents in the recovery phases of AMI.

Risk stratification of the patient with AMI has been an area of considerable interest over the past decade. Exercise testing has been advocated as a valuable method of identifying the high-risk patient.[9] According to this survey, 83% of physicians routinely perform exercise testing for their patients with uncomplicated AMI. It has been proposed that risk stratification of the patient with AMI can be further refined by testing to document electrical instability and left ventricular dysfunction.[10] This survey indicated that most physi-

cians have remained selective in their use of 24-hour ambulatory monitoring, radionuclide ventriculography and thallium scintigraphy, recommending these procedures in less than half of their patients (Table I).

One clear trend documented in this survey was the widespread acceptance of coronary angiography in patients with uncomplicated AMI (Table II). Coronary angiography was more likely to be used in younger patients, with its use in patients <45 increasing considerably between 1979 and 1987. Coronary angiography was also recommended frequently in patients with jeopardized myocardium, such as those with positive exercise tests, previous intravenous thrombolytic therapy or a non-Q-wave AMI. These data suggest that physicians are attempting to identify patients for possible coronary revascularization. Due to space limitations, we were not able to explore the indications for coronary artery surgery or coronary angioplasty after uncomplicated AMI, but the available data suggested that most physicians have adopted an aggressive approach toward revascularization therapy.

Some of the largest shifts in practice documented in this survey were in the use of medications after hospital discharge. Routine use of β-adrenergic blocking agents rose from 35% in 1979 to almost 80% in early 1987. Furthermore, most physicians continue administering indefinitely β blockers to their patients. Several large randomized studies since 1979 have demonstrated that β blockers decrease mortality in patients after AMI.[8,11] Our findings suggest that these randomized studies have successfully modified the standard of practice across the U.S.

A surprising finding was that over 80% of respondents routinely recommend aspirin for patients after uncomplicated AMI, almost double the rate found in the 1979 survey. Since 1979, many studies have demonstrated the importance of thrombotic occlusion of a coronary artery in the etiology of AMI.[12] Two large randomized trials have demonstrated that low doses of aspirin prevent AMI and death in patients with unstable angina.[13,14] Several large randomized trials of aspirin after AMI failed to demonstrate statistically significant results individually, but when pooled they suggested a decrease in mortality in aspirin-treated patients after AMI. In view of this evidence, the Food and Drug Administration in 1985 approved use of aspirin as secondary prophylaxis for patients after AMI.[15] The results of this survey strongly suggest that aspirin has been accepted by most physicians for this indication.

One of the more interesting changes in practice is the virtual abandonment of sulfinpyrazone, which also has antiplatelet properties, as a secondary preventive agent after AMI. In 1979, almost 15% of physicians used sulfinpyrazone, but by 1987 only 1% were still using it. In 1978, a randomized trial published in a major journal reported a reduction in sudden cardiac death after AMI in patients treated with sulfinpyrazone.[16] Certain methods used in this study, however, sparked a major controversy,[17,18] which appears to have introduced sufficient doubt about the efficacy of sulfinpyrazone that its use has essentially been abandoned. The change is all the more remarkable given the increased acceptance of the platelet active agents aspirin and dipyridamole in the postinfarction setting.

This study, like all surveys, has certain inherent limitations. First, the data represent what physicians say they do in practice, rather than being an actual audit of their practices. Second, many physicians did not respond to the survey. Since relatively more cardiologists responded than internists or family and general practitioners, our results are reported according to specialty. Clearly, the nonrespondents may differ from the respondents in other ways, and caution must be used in extrapolating these results to all physicians. However, since the analysis of time trends is referenced to previous surveys, which share these same limitations, we believe the trends reported here reflect true shifts in practice patterns.

Influence of Long-Term Metoprolol Treatment on Early and Late Exercise Test Performance After Acute Myocardial Infarction

GUNNAR OLSSON, MD, PhD, NINA REHNQVIST, MD, PhD,
ULLA FREYSCHUSS, MD, PhD, and STAFFAN ZETTERQUIST, MD, PhD

The effect of therapy on exercise performance during a 3-year follow-up after acute myocardial infarction (AMI) was evaluated in a double-blind randomized comparison between 154 patients given metoprolol (100 mg twice daily) and 147 patients given placebo. Exercise tests were performed 1.5, 6, 12, 24 and 36 months after AMI. Maximal accomplished workloads were similar in the 2 groups throughout follow-up. Maximal heart rate was significantly higher in the placebo-treated group throughout the study ($p < 0.001$). At the 6-week test more patients in the placebo group terminated exercise due to angina pectoris (40 vs 25%, $p < 0.05$) and showed exercise-induced ST-depressions (38 vs 27%, $p = 0.05$) compared with the metoprolol group. Exercise-induced ventricular arrhythmias were significantly more common in the placebo group during the initial 6 months. Death, another AMI or both were significantly reduced by metoprolol treatment in patients with exercise-induced ST depression ≥ 1 mm at the 6-week test. In a multiple logistic regression analysis maximal accomplished workload at 6 weeks ($p < 0.026$), male sex (relative risk [rr] = 3.57, $p = 0.016$), previous AMI (rr = 3.07, $p = 0.001$), therapy with placebo (rr = 2.14, $p = 0.007$) and left ventricular failure (rr = 2.04, $p = 0.023$) were shown to carry independent prognostic information as well as exercise-induced ST-depression (≥ 1 mm) in placebo-treated patients (rr = 2.70, $p = 0.01$).

(Am J Cardiol 1988;61:519–523)

In recent years post-acute myocardial infarction (AMI) trials have convincingly shown that treatment with certain β blockers improves prognosis.[1] It is, however, important to investigate other potential effects of treatment, such as symptoms and physical fitness. The present study investigates certain aspects of post-AMI treatment with metoprolol. The effects of the treatment on ventricular arrhythmias and prognosis have previously been published.[2–4] In this report we describe the effect of post-AMI metoprolol treatment on performance on repeated exercise tests during a 3-year follow-up. The prognostic value of an exercise test performed 6 weeks after AMI was also evaluated and the possible influence of metoprolol treatment was analyzed.

Methods

The Stockholm Metoprolol Trial was a prospective, double-blind, placebo-controlled study of patients after AMI. A detailed description of the study has been reported previously.[3] In brief, 301 survivors of AMI younger than 70 years of age, in sinus rhythm and without bundle branch block or contraindications for β blockade were stratified prospectively according to ventricular arrhythmias on a long-term electrocardiographic registration, infarct size as estimated by enzyme maximum and age. Thereafter the patients were randomized to 3 years of double-blind treatment with metoprolol 100 mg twice daily (n = 154) or placebo (n = 147). Treatment started 7 to 14 days after the acute event. No patient was lost during the follow-up as regards information on mortality and morbidity. Patients were included between May 1976 and December 1980.

TABLE I Baseline Characteristics

Variables	Placebo (n = 147)	Metoprolol (n = 154)
Mean age (yrs)	59 ± 7	60 ± 7
Men (%)	83	78
Previous AMI (%)	20	21
History of SH (%)	28	23
Cerebrovascular event before AMI (%)	3	5
Q-wave AMI (%)	72	75
Site of AMI		
Anterior (%)	51	44
Inferior (%)	31	38
Unknown (%)	18	18
LDH_t (ukat/liter)	19.6 ± 13.7	19.8 ± 14.0
VF in CCU (%)	3	3
Rales in CCU (%)	67	65
SBP <90 mm Hg in CCU (%)	10	10
Complex VPCs at randomization (%)	33	38
Treatment at discharge		
Digitalis (%)	24	23
Diuretics (%)	48	42
Antiarrhythmics (%)	6	6

AMI = acute myocardial infarction; CCU = coronary care unit; LDH_t = peak value of the thermostable fraction of lactate dehydrogenase; SBP = systolic blood pressure; SH = systemic hypertension; VF = ventricular fibrillation; VPCs = ventricular premature complexes.

Patients were withdrawn from study treatment if there was an obvious need for β blockade or if suspected severe side effects developed.[3] All surviving patients were followed for the entire 3 years. Exercise tests were performed 6 weeks and 6, 12, 24 and 36 months after the AMI with bicycle ergometer (Siemens-Elema). The workload started with 20 watts and increased by 10 watts/min[5] until limiting symptoms, hemodynamically important ventricular arrhythmias or severe ST depression (>4 mm) appeared. The following parameters from the exercise tests were used in the analysis: maximal workload, exercise limiting factor (angina pectoris, dyspnea, serious arrhythmia, severe ST depression, fatigue), maximal heart rate, exercise-induced ST depression ≥1 mm (0.1 mV) 0.06 second after the J point and ventricular arrhythmia during the test.

All patients gave their informed consent for participation in the study, which was approved by the local ethical committee.

Statistical analysis: In the statistical analyses the Student *t* test was used to compare continuous variables. In text data are presented as mean ± standard deviation. For comparisons of categorical variables the chi-square test was used. To evaluate the prognostic value of the 6-week exercise test a multiple logistic regression analysis was performed. In this analysis baseline characteristics as well as parameters obtained from the 6-week exercise test were included and tested for (1) death and (2) another AMI, death or both. All statistical analyses were performed in 2-tailed fashions. A p value <0.05 was considered significant. All statistical analyses have been performed according to initial drug allocation ("intention to treat"), unless otherwise stated.

Results

The 2 treatment groups were well balanced with no significant differences in pretreatment variables (Table I). Detailed mortality and morbidity data have been reported elsewhere,[3] but for clarity we will give a brief summary. There were 31 deaths (29 cardiac) in the placebo group compared with 25 (20 cardiac) in the metoprolol group (difference not significant). Thirty-one placebo-treated patients had another nonfatal AMI, compared with 18 in the metoprolol group (p <0.05). During the 3 years, 35 and 38 patients in the placebo and metoprolol groups, respectively, were withdrawn from study treatment.[3]

At the 6-week test calcium antagonists were given to 17 placebo patients (7 verapamil, 6 nifedipine, 4 prenylamine) and to 4 (p <0.05) metoprolol patients (1 nifedipine, 3 prenylamine). Corresponding numbers for long-acting nitrates were 32 and 17 (p <0.05).

Exercise tests: In 25 patients the initial 6-week exercise test is missing (8 placebo and 17 metoprolol). The reasons for missing tests in the placebo group are:

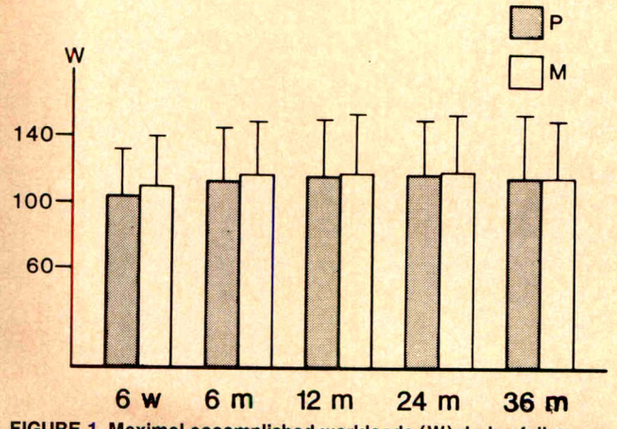

FIGURE 1. Maximal accomplished workloads (W) during follow-up. M = metoprolol; m = months; P = placebo; w = weeks. Number of patients as in Table II.

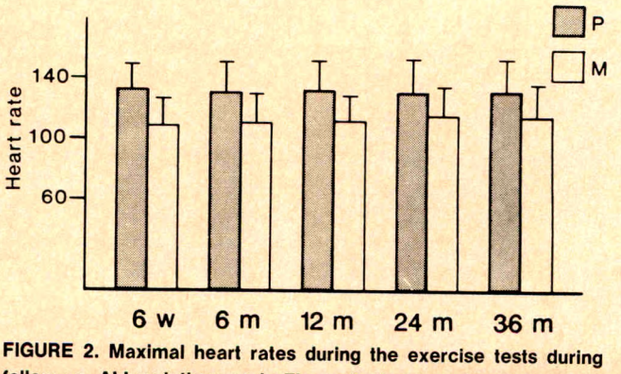

FIGURE 2. Maximal heart rates during the exercise tests during follow-up. Abbreviations as in Figure 1. Number of patients as in Table II. The differences between the 2 groups were significant (p <0.001).

TABLE II Reasons for Termination of Exercise Tests

	Placebo						Metoprolol					
	No.	Angina	Dyspnea	Arrhythmia	ST↓	Fatigue	No.	Angina	Dyspnea	Arrhythmia	ST↓	Fatigue
6 weeks (%)	139 (88)	40 (33)	19 (18)	2 (2)	4 (7)	35 (40)	137 (92)	25* (24)	25 (23)	2 (3)	3 (3)	45 (47)
6 months (%)	133 (88)	25 (23)	26 (27)	2 (2)	3 (3)	44 (45)	140 (92)	24 (18)	21 (21)	1 (1)	3 (3)	51 (57)
12 months (%)	127 (86)	30 (27)	24 (27)	2 (0)	2 (2)	42 (44)	137 (93)	23 (23)	18 (16)	1 (0)	3 (3)	55* (58)
24 months (%)	112 (83)	27 (25)	20 (23)	2 (2)	3 (1)	48 (49)	129 (90)	21 (16)	27 (27)	1 (1)	2 (2)	49 (54)
36 months (%)	105 (83)	33 (32)	23 (24)	2 (2)	1 (1)	41 (41)	122 (92)	21 (17)*	30 (31)	1 (1)	0 (0)	48 (51)

Values derived according to "intention to treat"/"on drug 36 months."
* $p < 0.05$ compared with placebo group.
ST↓ = ST-segment depression.

4 deaths, 2 due to arrhythmia, 1 unwillingness, 1 unknown cause. In the metoprolol group the following reasons for missing tests are: 6 deaths, 2 re-AMI, 3 unwillingness and 6 unknown causes. Two and 4 patients in the placebo and metoprolol groups, respectively, with missing tests subsequently died.

Maximal workloads at the 6-week test were 104 ± 29 and 110 ± 32 watts in the placebo and metoprolol groups, respectively (difference not significant). Maximal workload increased significantly to maximum values of 117 ± 34 and 119 ± 37 in the 2 groups, respectively, at 24 months. Maximal accomplished workloads in the 2 groups are shown in Figure 1.

Maximal heart rate at the 6-week exercise test was 133 ± 17 beats/min in the placebo group and 109 ± 19 beats/min in the metoprolol group ($p < 0.001$). During the follow-up maximal heart rate was always lower in the metoprolol group compared with the placebo group ($p < 0.001$, Figure 2).

Reasons for termination of exercise tests are shown in Table II. In the placebo group there was a significantly larger proportion of patients terminating due to angina at the 6-week test than in the metoprolol group (40 vs 25%, $p < 0.05$). At 12 months a significantly larger proportion of patients terminated exercise due to fatigue in the metoprolol group than in the placebo group (55 vs 42%, $p < 0.05$). When analyzing patients who actually continued to receive study treatment ("on drug 36 months"), more patients in the placebo group experienced angina pectoris during exercise at 36 months (32 vs 17%, $p < 0.05$).

In the placebo group 38% of the patients showed ≥1 mm ST-depression during the 6-week test. The corresponding figure in the metoprolol group is 27% ($p = 0.05$). The rate of mortality, another AMI or both among patients with ST depression ≥1 mm was 45% in the placebo group and 22% in the metoprolol group ($p < 0.05$). Corresponding figures for patients without ST depressions are 15 and 9%, respectively (difference not significant).

During the exercise test at 6 weeks 48% of the placebo patients showed any type of ventricular arrhythmia compared with 28% of the metoprolol patients ($p < 0.001$). The corresponding figures at the 6-months test were 45% and 31% ($p < 0.05$). The proportions of patients with ventricular arrhythmia during exercise are shown in Figure 3.

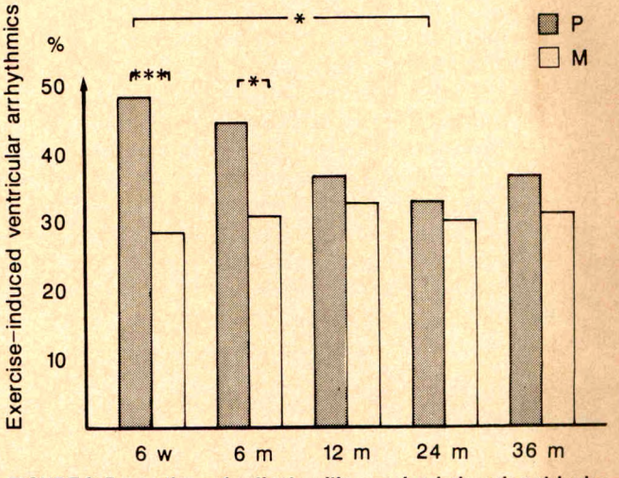

FIGURE 3. Proportions of patients with exercise-induced ventricular arrhythmias during follow-up. Abbreviations as in Figure 1. Number of patients as in Table II. * $p < 0.05$; *** $p < 0.001$.

Prognostic implications from the six-week exercise test: In the multiple logistic regression analysis the following variables were entered: treatment group, sex, smoking habits, previous AMI, type of index AMI, signs of left ventricular failure in the coronary care unit, digitalis and diuretic treatment at discharge, complex ventricular arrhythmias at a predischarge 6-hour electrocardiographic recording, age and LD_t-maximum (peak value of thermostable fraction of lactate-dehydrogenase). From the 6-week exercise test, ventricular arrhythmia, exercise-limiting factor, ≥1 mm ST depression and maximal workload were used.

When death was set to be the dependent variable, previous AMI (relative risk [rr] 3.07, $p = 0.001$), maximal workload ($p = 0.026$) and male sex (rr 3.57, $p = 0.016$) were found to carry significant prognostic information for the following 3 years for the entire data base (i.e., the 2 treatment groups taken together). In this model the value for "goodness of fit" was 0.829. For the prediction of death, another AMI or both, the following variables carried significant prognostic weight: previous AMI (rr 2.76, $p = 0.002$), placebo treatment (rr 2.14, $p = 0.007$), heart failure in the coronary care unit (rr 2.04, $p = 0.023$) and male sex (rr 2.32, $p = 0.044$). The "goodness of fit" was 0.957.

In a second step, the multiple logistic regression analysis was applied to the 2 separate treatment groups to derive information on treatment influence on risk indicators. In this analysis ST depression ≥1 mm was shown to be an independent risk indicator for death, another AMI or both in the placebo group (rr 2.7, p = 0.01). In the metoprolol group, however, ST depression was not associated with worsened prognosis.

Any major cardiac event among patients with angina at the 6-week exercise test was significantly more common in the placebo group (23 of 55, 42%) than in the metoprolol group (5 of 34, 15%) (p <0.01). In the placebo group these events consisted of another AMI in 10 patients (2 subsequently died), deaths in 9 and coronary artery bypass grafting in 4. Corresponding figures in the metoprolol group were 1, 2 and 2. In patients who did not experience angina during the initial exercise test, any major cardiac event occurred in 29 (35%) and 19 (19%) patients in the placebo and metoprolol groups (p <0.05), respectively. These events consisted of another AMI in 18 patients (6 subsequently died), deaths in 8 and 3 underwent coronary artery bypass grafting. Corresponding figures in the metoprolol group were another AMI in 9 patients (4 subsequently died), deaths in 9 and coronary artery bypass grafting in 1. In a separate univariate analysis in patients without previous AMI, mortality was significantly reduced in the metoprolol patients (3.2 vs 7.7% in placebo, p <0.05).

Discussion

In the present study metoprolol treatment after AMI did not influence maximal workload. Similarly, timolol treatment after AMI has also been shown not to influence the working capacity.[6] Probably, these findings are partly explained by the large proportion of patients receiving both β blockers and placebo who terminate exercise because of reasons other than angina. Further, the more frequent use of other antianginal drugs in the placebo group may well have influenced the results. Despite this more frequent use of other antianginal drugs, angina during the 6-week exercise test was more common in the placebo than in the metoprolol group. At 6 months, however, no significant difference in exercise limiting factors was found between the groups. Interestingly, maximal workload was similar in the 2 treatment groups, although reasons for termination sometimes differed (e.g., at 6 weeks angina was more common in the placebo group, at 12 months fatigue was more common in the metoprolol group).

Exercise-induced ventricular arrhythmias were more common in the placebo group during early follow-up. These findings are in agreement with previous reports.[7,8] The clinical significance of this finding is not clear. When ventricular arrhythmias were recorded by repeated Holter monitorings,[2] we noted another pattern. Continuous increases in both complexity and frequency of ventricular arrhythmias by time in the placebo group occurred. These increases were counteracted by metoprolol treatment. However, in that evaluation an early decrease in premature ventricular complexes was indeed seen by metoprolol therapy, indicating also an acute antiarrhythmic action.

In patients who actually continued to receive study treatment throughout the 3 years, the proportions of patients with angina as limiting symptom initially after the AMI were similar in the 2 groups. At 3 years, however, significantly more patients in the placebo group terminated exercise due to angina. These results—in combination with the improved prognosis in patients treated with metoprolol and the effect on chronic ventricular arrhythmias[2]—may indicate that the course of the disease is positively influenced by β-adrenoceptor blockade. Whether this reflects influence on the underlying disease or only the manifestations of the disease is yet unclear.

In several previous studies the prognostic information of an exercise test after AMI has been evaluated. Thus, the prognostic importance of ischemia-induced electrocardiographic abnormalities,[9–18] exercise-induced ventricular arrhythmias,[12,19–22] abnormal blood pressure response[22,23] and functional capacity[9,22,24–27] has been shown. In the present study maximal workload carried independent prognostic value in the entire material. In the placebo group exercise-induced ST depression ≥1 mm also carried significant prognostic information. Interestingly, this was not found in the metoprolol group, similar to results from Krone et al.[18] Other clinical factors with independent prognostic weight were sex, previous infarction, therapy without β blockers and left ventricular impairment.

Metoprolol treatment in patients with signs of ischemia (angina or ST depressions) was beneficial. However, active treatment also improved prognosis in so-called low-risk patients, that is, those without angina pectoris or previous infarction.

In conclusion, treatment with metoprolol after AMI does not influence maximal exercise capacity. Exercise-induced angina and ST depression early after AMI are reduced by metoprolol. Maximal workload at 6 weeks, male sex, previous infarction, therapy without β blockers and left ventricular heart failure carry prognostic information. Exercise-induced ST depression in patients who are not treated with β blockers also has prognostic value, but not in those treated with β blockers.

Improved Survival up to Four Years After Early Coronary Thrombolysis

DETLEF G. MATHEY, MD, JOACHIM SCHOFER, MD, FLORENCE H. SHEEHAN, MD, HANS-JOACHIM KREBBER, MD, MARLENE JUSTEN, MD, GEORG RODEWALD, MD, H.T. DODGE, MD, and WALTER BLEIFELD, MD

The long-term prognosis after thrombolytic therapy in patients with acute myocardial infarction (AMI) is unknown. This question was investigated in a 4-year follow-up study of 227 patients. According to the status of reperfusion at the end of the acute catheterization, the patients were divided into a patent (n = 171) and an occluded (n = 56) group. Both hospital and 4-year mortality rates were significantly reduced in the patent group by 13 and 14%, respectively ($p \leq 0.005$ for both). Baseline variables known to be important for prognosis did not differ between the 2 groups. Patients with a patent infarct artery who underwent early acute coronary artery bypass grafting (CABG) had a greater survival ($p < 0.10$) and better left ventricular function ($p < 0.01$) than did patients with a patent infarct artery who did not undergo CABG. This difference was associated with a lower frequency of fatal reinfarction and cardiogenic shock in the CABG group. Thus, survival is improved up to 4 years after successful thrombolysis and appears to be further enhanced by early CABG.

(Am J Cardiol 1988;61:524–529)

Several years after its introduction,[1–3] intracoronary and intravenous thrombolytic therapy clearly shows a positive effect on hospital mortality[4,5] in acute myocardial infarction (AMI). In addition, 1-year follow-up results have been reported from 2 trials.[6,7] Whereas the initial reduction in hospital mortality was fully maintained in the Dutch trial,[7] it was partly lost in the Western Washington trial[6] by 1 year. In both trials, a substantial proportion of patients underwent revascularization by either percutaneous transluminal coronary angioplasty (PTCA) or coronary artery bypass grafting (CABG). Long-term prognosis beyond 1 year, however, is unknown. This study observed patients up to 4 years after thrombolytic therapy and analyzed the factors contributing to their survival.

Methods

Patient population: Patients with AMI were enrolled in the study, if they were admitted within 3 hours of the onset of chest pain and had ≥2 mm ST-segment elevation on the electrocardiogram. They underwent immediate (onset of treatment ≤5 hours after symptom onset) thrombolytic therapy with intracoronary streptokinase between 1979 and 1983 (n = 174) or intravenous urokinase during 1983 and 1984 (n = 56).[8,9] Patients receiving intravenous urokinase were studied within 1 hour after initiation of therapy. PTCA was performed in 19 patients with severe residual stenosis after thrombolytic therapy. Reperfusion was achieved by PTCA in 17 of 25 patients whose infarct artery remained occluded after thrombolytic therapy.

Clinical follow-up: Between April 1985 and April 1987, patients were contacted to determine vital status, and the date of death or rehospitalization, if applicable. Reinfarction was defined as an infarct that occurred in the same location as when the patient was enrolled in the study and was diagnosed on the basis of typical electrocardiographic and enzyme changes. The cause of death and the reason for rehospitalization were determined from the patient's medical record. Data on vital status could be obtained in 227 (99%) of the 230 consecutively enrolled patients.

* Chi square for dichotomous variables, unpaired *t* test for continuous variables, differences are significant if $p < 0.05$, but p values > 0.05 and < 0.10 are included for interest.

† Parentheses indicate number of patients if data are incomplete.

CCU = coronary care unit; ECG = electrocardiogram; LV = left ventricular; MI = myocardial infarction; NS = difference not significant; SD = standard deviation from normal; VF = ventricular fibrillation; VT = ventricular tachycardia.

CABG was defined as early if performed within 14 days after AMI. The indications for early CABG were: (1) a patent infarct artery with a residual stenosis >70% in conjunction with recurrent ischemic events, scintigraphic evidence of myocardial salvage, or both and (2) severe lesions in other vessels limiting prognosis (left main disease or left main equivalent).

In patients undergoing CABG <24 hours after thrombolysis, care was taken to prime the heart lung machine with 2 to 3 units of whole blood to improve the coagulation status. Two patients received supplemental infusions of fibrinogen.[10]

Angiographic analysis: The severity and the extent of coronary artery disease and the patency of the infarct artery were assessed visually by the consensus of 2 observers. Patency immediately after thrombolysis was defined as complete opacification of the infarct artery with normal rates of filling and clearing of contrast. Patients with only partial reperfusion, that is, incomplete artery opacification, or slow filling or clearing of contrast, were not considered to be successfully reperfused.

Left ventricular (LV) function was analyzed at the University of Washington from the cine films. LV volume was calculated by the area-length method. Wall motion abnormality in the infarct and noninfarct regions was calculated by the centerline method and expressed in standard deviations per chord as previously described.[11]

Scintigraphic studies: In 69 patients, who were admitted when the isotope and nuclear medicine personnel were available, intracoronary myocardial scintigraphy with thallium-201 was performed in the catheterization laboratory using a mobile gamma camera before and immediately after thrombolysis.[12] Scintigraphic evidence of myocardial salvage was defined as significant new thallium uptake with no or only a small residual thallium defect as judged by 2 independent observers.

Statistical analysis: Comparisons between patient groups were performed using the unpaired *t* test for continuous variables and chi-square for dichotomized variables. The change in LV function between acute and follow-up study was assessed using paired *t* test. Differences in long-term survival were assessed using life table analysis. The contribution of factors to survival was evaluated using *t* test for continuous variables, and chi-square or Fisher's exact test for dichotomous variables. Statistical significance was defined as $p < 0.05$; however, p values > 0.05 and < 0.10 are included for interest.

Results

Identification of factors influencing survival: Table I lists clinical variables evaluated for their correlation with vital status. Patients who died differed significantly from those who survived in age, sex, arrhythmia in the cardiac care unit, history of angina, systemic hypertension, previous AMI, infarct artery patency and whether or not CABG was performed early. Although data were not complete for these parameters, bias is unlikely because the occurrence of missing data was similar for survivors and nonsurvivors. LV function measured acutely was also significantly more depressed in patients who died; for this parameter the actual differences may be greater because ventriculography was omitted in the majority of patients who subsequently died.

TABLE II Characteristics of Patients With and Without a Patent Infarct Artery

	Patent	Not Patent	p Value
Pts (n)	171	56	
Mean age (yrs)	55 ± 12	58 ± 11	NS
Men (%)	84	77	0.090
Infarct location, % anterior	58	62	NS
Coronary disease, % 1-vessel	36	32	NS
Q wave on admission ECG (%)	33 (130)	29 (42)	NS
Maximum ST-segment elevation (mm)	4.4 ± 3.9 (127)	4.0 ± 3.0 (41)	NS
Arrhythmias in CCU (% none/VT/VF)	68/17/15 (119)	54/14/32 (35)	0.095
LV ejection fraction (%)	53 ± 13 (125)	52 ± 13 (26)	NS
Hypokinesis in infarct site (SD)	−2.5 ± 1.0 (125)	−2.5 ± 1.6 (26)	NS
Hyperkinesis in noninfarct site (SD)	0.7 ± 1.5 (125)	0.5 ± 1.5 (26)	NS

Abbreviations as in Table I.

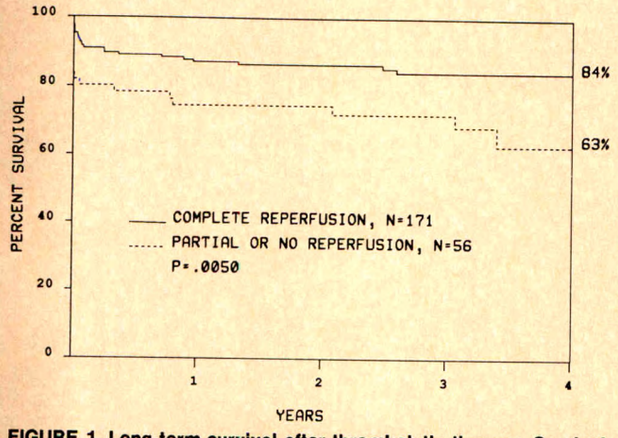

FIGURE 1. Long-term survival after thrombolytic therapy. Survival was significantly ($p \leq 0.005$) greater in patients who had a patent infarct artery at the end of the acute cardiac catheterization than in patients with partial or no reperfusion.

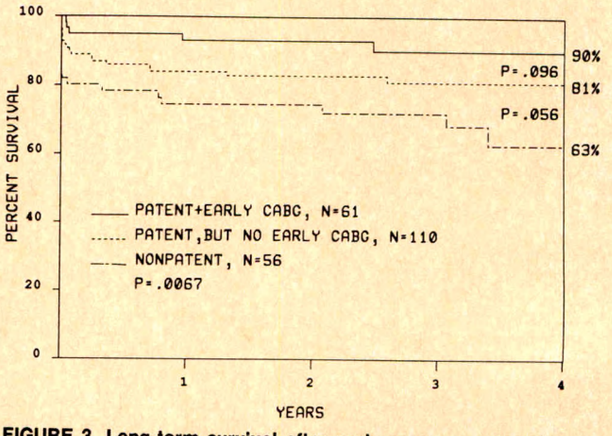

FIGURE 3. Long-term survival after early coronary artery bypass surgery (CABG). Patients who underwent surgery within 14 days after infarction had better survival than those without reperfusion or those with a patent infarct artery but who did not undergo CABG.

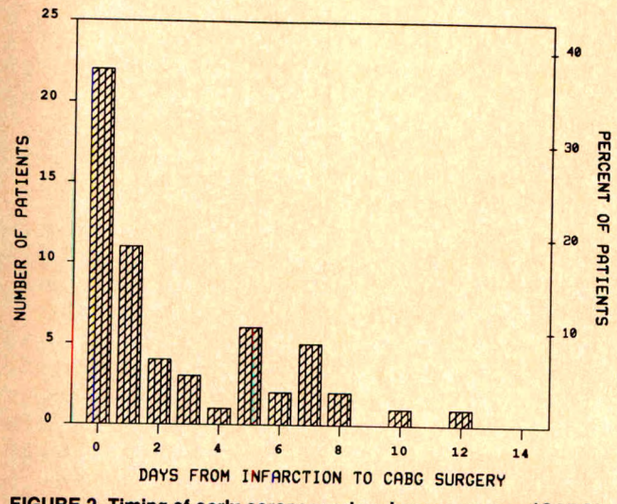

FIGURE 2. Timing of early coronary artery bypass surgery (CABG). Most patients were operated on within the first 2 days after infarction.

Coronary artery patency: Survival was significantly better ($p < 0.005$) in patients who achieved a patent infarct artery at the end of the acute cardiac catheterization than in those with an occluded artery (Figure 1). This difference was apparent at 10 days and was maintained up to 4 years after AMI. The baseline characteristics of these 2 groups did not differ before thrombolysis (Table II). After thrombolysis, early CABG was performed more frequently in patients with a patent infarct artery (Table III).

Early coronary artery bypass grafting in patients with patent infarct arteries: Early CABG was usually performed in the first 2 days after AMI (Figure 2). On the average, 2.6 grafts per patient were implanted, 92% of which were angiographically patent at follow-up approximately 1 month later. Despite abnormal coagulation values at the beginning of surgery in most patients, the intra- and postoperative blood loss was not greater in patients operated on the day of thrombolysis than in those operated later.[13] Hospital mortality in the operated patients was 3.2%.

TABLE III Follow-Up Characteristics of Patients With and Without a Patent Infarct Artery

Abbreviations as in Table I.

Patients with a patent infarct artery who underwent early CABG had a 90% 4-year survival rate; there was an 81% survival rate in the patent nonoperated group (Figure 3) ($p = 0.096$). The poorest survival (63%) was seen in patients with occluded infarct arteries ($p < 0.06$ vs nonoperated).

Because it was used as a criterion for early CABG, perfusion on thallium scintigraphy was more frequently improved in patent, operated than in nonoperated patients. However, the residual perfusion defect after thrombolysis was large in both groups. There was no significant difference between the operated and nonoperated groups in any of the other baseline characteristics tested, nor were there significant intergroup differences in the incidence of missing data (Table IV). However, LV function at follow-up was significantly better in the operated patients (Figure 4). Wall motion in the infarct region improved only in the operated patients. Motion in the noninfarct region remained hyperkinetic in operated patients instead of decreasing to normal levels by follow-up, as it did in the nonoperated group. This resulted in a higher follow-up ejection fraction in the operated patients of 57 ± 12 ($n = 36$) versus 50 ± 12% ($n = 73$) in nonoperated patients ($p < 0.01$).

Causes of death: Forty-two patients died. Of those who died of cardiogenic shock only 1 was in the operated group compared with 4 in the patent, nonoperated group and 7 in the occluded group. Death by reinfarction occurred in 6 patients in the patent, nonoperated group but only 1 in the operated group.

Rehospitalization: The rate of rehospitalization (Figure 5) for cardiac indications, such as angina, congestive heart failure, arrhythmias or reinfarction, was only 13% over the 4-year period, and was similar in the operated, patent nonoperated and occluded groups.

Discussion

This study is the first to observe and report long-term survival after thrombolysis. The data indicate that survival is significantly better up to 4 years after AMI in patients in whom a patent infarct artery is achieved compared with patients in whom the infarct artery remains occluded. Patients who undergo early CABG after successful thrombolysis because of a high-grade residual stenosis in conjunction with scintigraphic evidence of myocardial salvage, recurrent ischemic events or severe, multivessel disease have a

higher survival rate than patients with successful thrombolysis but who do not undergo CABG.

The difference in survival between our patients with complete reperfusion compared with those with persistent occlusion or partial reperfusion agrees with data from the Western Washington trial[6] showing significantly greater survival after complete reperfusion than after partial or no reperfusion. Could factors other than infarct artery patency explain this difference in survival? Baseline characteristics known to be important for prognosis did not differ significantly between the patent and the occluded group. Thus, the 2 groups were comparable before thrombolysis. After thrombolysis, a reduction in infarct size in the patent group may have been responsible for their better prognosis, because they had better LV function and slightly lower peak creatine kinase levels. That successful thrombolytic therapy may also benefit function in the noninfarct region has been observed in other trials.[14,15] The lack of a significant difference in LV function is probably due to the frequent omission of ventriculography in patients who had an occluded artery. The most significant difference between the 2 groups was the higher incidence of early CABG in the patent group.

When the patient with a patent infarct artery were further subdivided according to whether they underwent early CABG, the CABG group was found to have better survival. Because the patients were not randomly assigned to early CABG but were selected according to the indications mentioned, it is difficult to give a definite explanation for this observation from our study. Some aspects, however, can help to clarify the problem. First, the baseline characteristics did not differ significantly between the operated and patent but nonoperated groups, although operated patients tended to be younger. Instead, there was greater risk in the operated group due to the significantly higher incidence of previous AMI. Second, performance of early CABG was not associated with undue morbidity and mortality.[13] Thus, since baseline characteristics and complications of surgery cannot explain the survival difference, this difference is most likely due to the effect of therapy. The enhanced survival in the operated group may be due to myocardial salvage resulting from better perfusion or the protective effect of early CABG or both. As evidence for myocardial salvage,

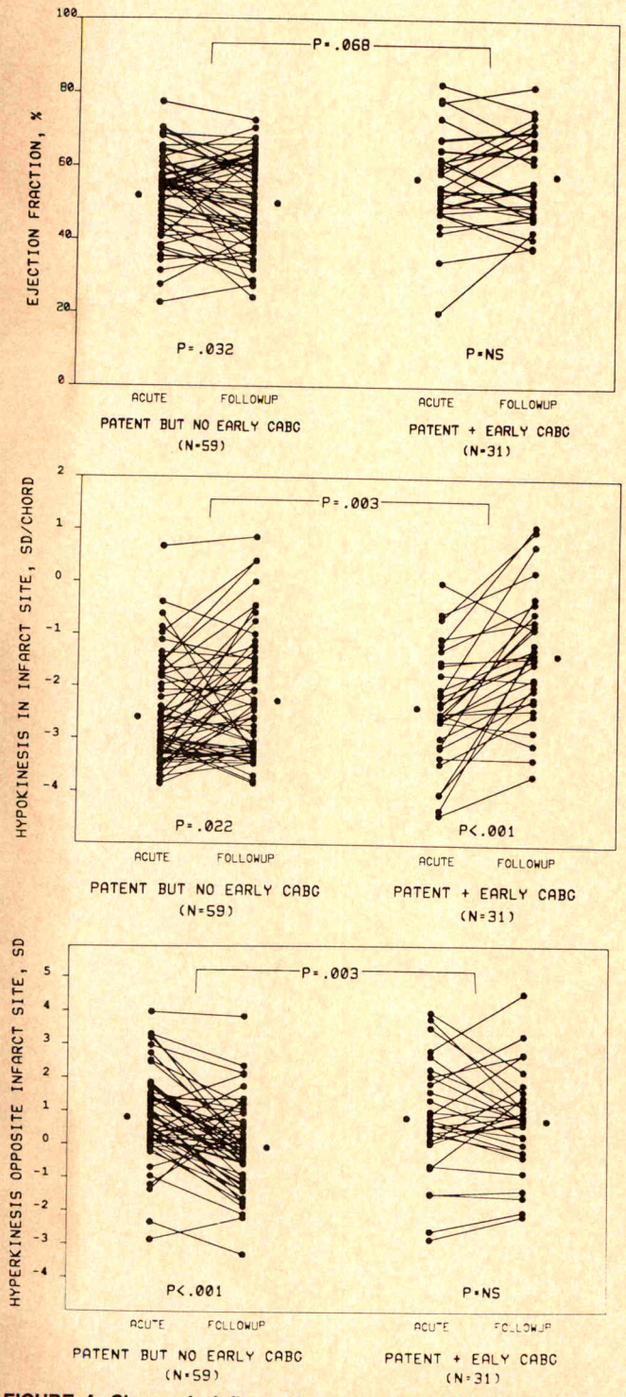

FIGURE 4. Change in left ventricular function after thrombolytic therapy ± coronary artery bypass surgery (CABG). The influence of hypokinesis in the infarct region and hyperkinesis in the noninfarct region on the global ejection fraction can be seen.

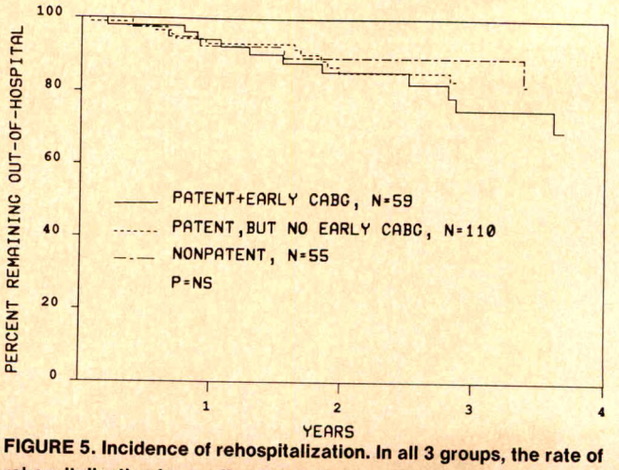

FIGURE 5. Incidence of rehospitalization. In all 3 groups, the rate of rehospitalization for cardiac indications was similarly low. CABG = coronary artery bypass grafting.

LV function at follow-up was significantly greater in the operated group. Because effective thrombolytic therapy exposes the patient to an increased risk of recurrent AMI,[7] the lower incidence of death by reinfarction among our operated patients suggests that early CABG enhanced survival by maintaining the beneficial effect of thrombolysis.

Factors of Importance for Prognosis in Men with Angina Pectoris Derived from a Random Population Sample

The Multifactor Primary Prevention Trial, Gothenburg, Sweden

MARIANNE HAGMAN, MD, LARS WILHELMSEN, MD, KJELL PENNERT, BSc, and HANS WEDEL, PhD

A random population sample of middle-aged men from the Primary Prevention Trial was followed for 11.3 years from a first screening when different factors known to be associated with coronary artery disease (CAD) were analyzed. Men with uncomplicated angina pectoris (AP) (n = 167) derived from this population had an incidence of fatal and nonfatal CAD events 3 times higher than that of men without AP or myocardial infarction (n = 5,774). Men with myocardial infarction with or without AP had an incidence of CAD events 7 to 8 times higher than that of men without AP or myocardial infarction. Similar differences were found for new cases of uncomplicated AP (n = 128) and myocardial infarction detected at a second screening after 4 years and followed for 7.3 years. Pooled data from this series of men with uncomplicated AP showed the following factors to be associated in multivariate analysis with nonfatal or fatal CAD endpoints during follow-up: elevated serum cholesterol, elevated blood pressure, smoking and attack score. The risk increase associated with the first 3 factors was similar to the general population. These findings indicate that the same factors affecting prognosis after a first appearance of AP affect similarly patients with myocardial infarction and clinically healthy subjects. Preventive measures against these risk factors seem to be of similar importance among patients with AP, post-infarct patients and healthy subjects.

(Am J Cardiol 1988;61:530–535)

The natural history of angina pectoris (AP) was first studied approximately 70 years ago, with 1 of the most extensive series of AP cases from that time described by White.[1] The prognosis was from the beginning mostly described in terms of mortality and the studies were not representative for the total experience with the disease.[1–3] Beginning with the Framingham study, a more reliable view of the fate of the AP victim was presented in population studies.[4–6] Early findings indicated that high blood pressure, cardiac enlargement and pathologic findings in the resting electrocardiogram were related to an unfavorable prognosis and that a complicating myocardial infarction further increased the risk of a fatal outcome. The introduction of coronary arteriography and left ventriculography made it possible to relate the prognosis of AP to pathoanatomic changes. The more narrowed the coronary arteries and the more deranged the left ventricular

function, the worse was the prognosis.[7,8] This relation also has been established in cases with mild AP and myocardial infarction without AP.[9]

The present report comprises middle-aged men with AP, derived from a random population sample, followed during more than 10 years and subjected to comprehensive prospective analyses of various possible risk indicators.

Methods

All AP cases were derived from a screening examination of men born from 1917 to 1922 and from 1924 to 1925 (ages 47 to 54 at screening), performed in Gothenburg, Sweden, and constituting a random third of the men among these age-cohorts. Some general intervention measures such as treatment of high blood pressure dietary advice for men with elevated serum cholesterol and antismoking counseling were given according to previous reports.[10,11] Patients with AP received the same advice as the other participants of the study. There was no difference in myocardial infarction or stroke incidence or total mortality between this group and the controls.[12] The present study group comprised 167 men with AP not associated with myocardial infarction (uncomplicated AP), derived from the screening examination carried out between 1971 and 1973 and 128 men with uncomplicated AP detected at rescreening 4 years later (total = 295 men).

AP was diagnosed in a multistage procedure starting with a postal questionnaire on chest symptoms (an abbreviated form of the Rose questionnaire)[13] sent to the general population and followed by an interview by a physician at a screening examination for those responding positively to questions on chest pain. Those who were found to have definite or suspected AP were examined by 1 physician who further evaluated the diagnosis and followed most of the patients for the rest of the study. Smoking habits, known diabetes mellitus, intermittent claudication, dyspnea on effort, stress and physical activity at work and during leisure time were questions asked in the questionnaire and at the interview.[11]

Smoking habits were scored as follows: (1) nonsmoker; (2) ex-smoker; (3) smoking 1 to 14 g of tobacco/day; (4) smoking 14 to 24 g; (5) smoking ≥25 g. Tobacco amount was calculated thus: 1 cigarette = 1 g of tobacco, 1 cheroot = 2 g and 1 cigar = 5 g. Experience of stress was scored from 1, meaning "never felt stress," to 6, meaning "permanent stress during the last 5 years." Physical activity was scored from 1 to 4 from lowest to highest activity at work and during leisure (both times recorded separately). Systolic and diastolic blood pressure, total serum cholesterol, body height and weight were measured at the screening examination. Relative weight was calculated as:

$$\text{Weight (kg)}/(\text{height [cm]} - 100).$$

The angina attack score was registered for each patient according to the following scoring system: (1) no chest pain; (2) single attacks; (3) some attacks per month; (4) some attacks per week; (5) daily attacks; (6) daily attacks during summer as well as winter, not only at effort but also at rest or when walking on a plane.

A screening electrocardiogram with limb leads was followed by a full 12-lead registration during the clinical examination of those judged to have definite AP or suspected AP at the screening examination. The electrocardiograms were coded according to the Minnesota code by 2 independent medical technicians.[14] At a second screening. a 12-lead electrocardiogram was performed in all and the angina cases were coded as above. The occurrence of 1 or more of the following ischemic-type changes was analyzed: Minnesota code 1:1, 1:2, 1:3, 2:1, 3:1, 3:3, 4:1–4, 5:1–3, 7:1 or 8:3, or both.

Registration of endpoints such as nonfatal myocardial infarction and cause-specific mortality was done according to a standardized procedure but without the participation of the physician associated with the care of the AP patients. A special myocardial infarction register included all nonfatal myocardial infarctions according to standardized criteria since 1968.[15] All the death certificates of the city were collected by the organization every fortnight and deaths were also checked against the official national computerized death-certificate file. Causes of death were coded by 3 physicians using the same principles but being unaware of prior diagnosis and treatment. There was a 100% completion of follow-up regarding deaths (autopsy rate: 70% of in-hospital cases and 90% of outpatients), and more than 90% completion for nonfatal

TABLE I Incidence of Fatal and Nonfatal Coronary Artery Disease Events (11.3-Year Follow-Up)

myocardial infarction. All men were followed until March 31, 1983.

Statistics: Standard statistical methods were used to summarize and highlight all important data. Cox's regression analysis was used for the multivariate analyses. Fisher's exact test in fourfold tables was used to test the hypothesis of no difference in rates between 2 groups of patients. Pitman's nonparametric permutation test was used when testing continuous and graded variables. Only 2-tailed tests were performed and p values <0.05 were considered statistically significant.

Results

At the first examination, from 1971 to 1973, uncomplicated AP was diagnosed in 167 men and AP complicated with myocardial infarction in 58. Furthermore, another 39 men had already suffered a myocardial infarction not complicated with AP. All these subjects were followed for an average of 11.3 years and their outcome was compared with that in 5,774 men without AP or myocardial infarction (Table I). The percentage of cases suffering a fatal or nonfatal coronary artery disease (CAD) endpoint (myocardial infarction or sudden coronary death) during this time was significantly higher in the groups with AP or myocardial infarction than in the group free from CAD symptoms at entry. Those with complicated AP ran a significantly higher risk for an endpoint than those with uncomplicated AP.

At the second examination, from 1975 to 1977, AP had developed in another 162 men, 128 with uncomplicated AP and 34 with complicated AP. In addition, 68 new cases of myocardial infarction without AP had developed. All these subjects were followed for an average of 7.3 years and compared with 5,265 men without AP or myocardial infarction. Again, significantly more cases in the groups with AP or myocardial infarction reached a CAD endpoint during follow-up (Table II).

The follow-up study focused on the prognosis for men with uncomplicated AP. Among the 167 men with uncomplicated AP at first examination 32 suffered a fatal or nonfatal CAD event (11.3 year follow-up), and among the 128 subjects with uncomplicated AP at the second examination 18 had such an endpoint during follow-up (7.3-years follow-up). Thus, 50 cases in total reached a CAD endpoint.

Total mortality among those followed for 11.3 years was 19% (32 men), and for those followed for 7.3 years it was 12% (15 subjects), which was significantly higher than the percentages in those without AP or myocardial infarction: 8% for the groups followed for 11.3 years ($p < 0.001$) and 5% for those followed for 7.3 years ($p < 0.005$).

Among the 167 subjects followed for 11.3 years there were 2 variables measured at the first examination that differed significantly between the group developing a CAD endpoint and the group that did not: total serum cholesterol and systolic blood pressure (Table III). Among those who had an endpoint, 13% were receiving antihypertensive treatment compared to 4% who did not, although this difference was not significant. Among men with uncomplicated AP at the second examination the same variables were associated with risk for a CAD endpoint during follow-up (Table IV). At the second examination, 28% of those who later suffered an endpoint were receiving antihypertensive treatment compared to 22% among those who did not (the difference was not significant).

Smoking habits were not significantly associated with a CAD endpoint for any of the follow-up periods, but analyzed with a trend test for a smoking score of 1–5 an almost significant ($p = 0.058$) association was found for the follow-up period of 7.3 years.

Among the 167 men with uncomplicated AP at first screening, 152 full 12-lead electrocardiograms were available and coded (Table III). Even if all endpoint cases with missing electrocardiograms had abnormal electrocardiograms and all without endpoints and missing electrocardiograms had normal electrocardiograms, the difference would not have become significant ($p = 0.12$). At the second screening a full 12-lead electrocardiogram was performed in every subject. No significant relation between electrocardiographic changes and endpoint incidence was found (Table IV).

Scoring of AP attack frequency was missing in 5 of the 167 men with a follow-up time of 11.3 years and in 4 among the 128 men with 7.3 year follow-up. The men with mild AP (score 2–3) had a better prognosis than those with a score of 4–6 in the group with the longest

TABLE III Endpoint/Variable Relation During 11.3-Year Follow-Up

	CAD Endpoint				
	Present (n = 32)		Absent (n = 135)		p Value

Relative body weight (kg/cm − 100)	1.07	0.15	1.08	0.16	>0.20
Heart rate (beats/min)	74	12	74	15	>0.20

* Corresponds to 7.25 and 6.34 mmol/liter, respectively.
ECG = electrocardiogram; SD =standard deviation; other abbreviations as in Table I.

observation time (Table III). With the trend test (score 2–6), the same significance was noted ($p = 0.025$). In the second group, followed for 7.3 years, the attack frequency had no significant relation to prognosis (Table IV).

A pooling of the 2 groups with different follow-up times—including all 295 cases with uncomplicated AP—was also performed. Systolic and diastolic blood pressures and total serum cholesterol were significantly associated with outcome at univariate analysis, and the smoking habit was close to significant ($p = 0.067$).

Analyzing the data in a different way, we looked at prognosis among patients with AP who were nonsmokers or smokers, those who had low or high attack scores, and those with serum cholesterol and systolic blood pressure in different quartiles. The results for both follow-up periods were pooled (Table V). Data for men without AP or myocardial infarction are also included. The results show that the risk is generally 2 to 3 times higher for the patients with AP for any level of the risk factors.

Systolic blood pressure was positively correlated with serum cholesterol ($p < 0.05$), and serum cholesterol was also related to attack score ($p < 0.01$). The following variables were significant in Cox regression analysis: serum cholesterol ($p = 0.0007$), systolic blood pressure ($p = 0.0035$), smoking score ($p = 0.0053$) and attack score ($p = 0.035$).

In order to study in multivariate analysis the increase of risk for a CAD endpoint with increasing levels of the individual risk factors in AP men compared with men without AP or myocardial infarction, Cox regression analyses were performed. The variable attack score was excluded because it was available only for the men with AP. The β coefficients and their standard errors for cholesterol, systolic blood pressure and smoking among men with AP were 0.0101 (±0.0011), 0.020 (±0.006), and 0.338 (±0.048), respectively. Among men without AP or myocardial infarction, these variables changed to 0.0078 (±0.0011), 0.018 (±0.002), and 0.395 (±0.048), respectively. It then became obvious that the β coefficients for each factor were similar, indicating comparable relative risk gradients when men with AP were compared with healthy subjects.

There was a negative (nonsignificant) relation between smoking and systolic blood pressure in the present series, as well as in several population studies,[16,17] and also a negative (nonsignificant) relation between smoking and attack score. These facts may explain why smoking was not a significant predictor in univariate analysis but became significant in multivariate analysis.

TABLE V Prognosis at Start of Follow-Up

Variable	AP Patients		Men Without AP or MI	
	No. of Pts	Endpoint Incidence (%)	No. of Pts	Endpoint Incidence (%)
Attack score				
2	52	10		
3	72	11		
4	91	23		
5	38	16		
6	33	24		
Smoking habits				
Nonsmoker	68	10	1,611	3
Ex-smoker	69	13	1,132	4
Smoking 1–14 g/day	94	21	2,056	8
Smoking 15–24 g/day	54	22	826	9
Smoking ≥25 g/day	8	13	144	8
Total serum cholesterol*				
Quartile 1†	91	4	2,309	3
2	70	14	1,318	5
3	71	24	1,449	7
4	62	31	966	9
Systolic blood pressure*				
Quartile 1†	83	10	2,460	3
2	73	12	1,559	5
3	70	19	1,075	8
4	68	29	998	10

Patients detected at first screening (follow-up 11.3 years) and at second screening (follow-up 7.3 years) were pooled.

* The quartile cutoff points for serum cholesterol at both the first and the second screening were 229, 253 and 285 mg/dl, respectively (= 5.95, 6.75 and 7.41 mmol/liter), for systolic blood pressure at the first screening: 140, 154 and 168 mm Hg, respectively, and at the second screening: 134, 148, and 161 mm Hg, respectively.

† The quartile cutoff levels were calculated for the AP patients; that is why the numbers for men without AP or myocardial infarction differ between "quartiles."

Abbreviations as in Table I.

Discussion

Risk factors for CAD have been described in many studies.[6,12,16,17] During recent years, when sufficiently large population groups have been followed for sufficiently long periods, it has become evident that the risk factor pattern may differ between myocardial infarction and AP.[11,17] It also has been found that the "secondary" risk factors (or prognostic factors) *after* a myocardial infarction are different from those before such an event, at least during the first years. Thus, it has repeatedly been found that factors indicating large myocardial damage, number of infarcts and ventricular arrythmias are important prognostic factors during the first 3 to 4 years following the myocardial infarction.[18,19] However, when this period has passed, the "primary" risk factors seem to resume their importance, and elevated serum cholesterol, elevated blood pressure, tobacco smoking and diabetes become long-term prognostic factors.[20,21]

Several follow-up studies have shown that the number of diseased vessels and lesions in critical segments, such as the left main stem, as well as the signs of ventricular dysfunction (often unknown clinically), have important prognostic implications among AP patients and that corrections by means of coronary surgery may improve the prognosis considerably.[22–24] The importance of the myocardial factor becomes evident in the present study, when it shows that the incidence of CAD events among those who had a complicated AP was more than twice that of subjects who had an uncomplicated AP. Men with uncomplicated AP had a CAD event rate 3 times higher than that of men who were initially free from myocardial infarction or AP.

In population studies, all patients with varying degrees of symptoms have been included, ranging from those with minor symptoms (such that would not give rise to further diagnostic investigations), to those with severe symptoms (similar to the symptoms of patients included in angiographic series). Nowadays, many middle-aged men with AP may have undergone bypass surgery before inclusion in a population survey and thus bias the study sample. None of the present subjects had undergone bypass surgery before inclusion in the study. As it would not be ethically, clinically or economically justifiable to perform coronary angiography in all the patients in the present study, we were unable to determine the extent of the coronary artery lesions and their significance for prognosis. The relation to the attack score may, however, be taken as an indication of how important the degree of CAD is for prognosis.

One has to be cautious when drawing conclusions from studies like ours because of the relatively small number of endpoints: 50 CAD endpoints were available for study for the 2 periods with a total of 295 patients. This can be compared with a similar follow-up study performed on the Framingham data, in which 53 out of 130 men with uncomplicated AP experienced coronary attacks at a rate of 48.6/1,000 person-years of follow-up.[25] Such a number of endpoints is comparable to the present study but the incidence per 1,000 patient-years is more than double. To a large extent this difference may be explained by the much higher age of the subjects in the Framingham study. Our results are concurrent with the results of the Framingham Study[25] regarding blood pressure, but they did not find that high serum cholesterol was a significant risk factor even though the risk was somewhat higher among those with high cholesterol levels.

It is notable that high blood pressure was associated with a worse prognosis even though hypertensive men were treated when they were detected in the present study. In the total study sample comprising 7,495 men, the 5.9% prevalence of treated hypertension at the start of the study had increased to 26% after 10 years.[12] It would have been of interest to see whether more intensive blood pressure treatment also would have caused reduction (or increase) of the endpoint incidence, but such an analysis was not possible because of the small number of patients with AP and the fact that patients were not randomized to treatment. However, another analysis of the total sample of patients under antihypertensive treatment indicated that the degree of blood pressure reduction did not appreciably reduce endpoint incidence, whereas the prognosis

was positively affected by reductions of total serum cholesterol and smoking.[26]

Pathologic electrocardiographic findings have been of prognostic importance for AP patients in some studies,[23,25,27] but not in another.[9] Our findings concerning attack frequency are similar to those of the Whitehall study.[6] Patients with more severe AP had a worse prognosis, although this tendency has not been a consistent finding.[28]

In conclusion, we found that prognosis among patients with uncomplicated AP, in addition to attack score, was strongly dependent on the conventional risk factors for hard CAD events such as elevated serum cholesterol, elevated blood pressure and smoking habits. The findings indicate that preventive measures against these factors seem to be equally important for subjects with AP, clinically healthy subjects and patients with various manifestations of atherosclerosis.

Assessment of Mitral Flow Velocity with Exercise by an Index of Stress-Induced Left Ventricular Ischemia in Coronary Artery Disease

GEORGE D. MITCHELL, MD, RICHARD C. BRUNKEN, MD, MARKUS SCHWAIGER, MD, BRYAN C. DONOHUE, MD, JANINE KRIVOKAPICH, MD, and JOHN S. CHILD, MD

Exercise-induced myocardial ischemia results in both diastolic and systolic left ventricular (LV) dysfunction. To investigate the utility of Doppler assessment of LV diastolic function with exercise, 28 consecutive patients underwent digital stress echocardiography, including measurement of mitral flow velocity by pulsed-wave Doppler and simultaneous stress thallium imaging. The mean mitral flow velocity was measured as the integrated area under the LV diastolic inflow Doppler spectral display. The change in mean mitral flow velocity from baseline to immediate postexercise was compared among 3 patient groups: (1) patients with thallium redistribution or exercise-induced wall-motion abnormalities, or both, consistent with exercise-induced ischemia (n = 18), (2) patients with no evidence of stress-induced ischemia, with or without resting wall-motion abnormalities (n = 10), and (3) 10 control subjects of similar age with normal resting 12-lead electrocardiograms, normal resting and postexercise 2-dimensional echocardiograms and normal electrocardiographic treadmill stress testing. The percent increase in mean mitral flow velocity was 101% (±59) for controls and 86% (±53) for patients without stress-induced ischemia versus 33% (±24) in patients with stress-induced ischemia ($p < 0.005$). An increase in mean mitral flow velocity with exercise of >50% correctly identified 9 of 10 nonischemic control patients. An increase in mean velocity of <50% predicted ischemia in 15 of 18 patients with evidence of stress-induced ischemia ($p < 0.005$) Thus, Doppler assessment of LV diastolic function with exercise expressed as a change in the mean velocity of mitral flow is a useful indicator of stress-induced ischemia.

(Am J Cardiol 1988;61:536–540)

Studies have shown that exercise-induced myocardial ischemia can produce abnormalities in both diastolic and systolic left ventricular (LV) function.[1-5] Several methods have been used to assess diastolic function, including frame by frame analysis of contrast ventriculograms to determine rates of diastolic filling and analysis of time-activity curves obtained by gated blood pool scintigraphy to obtain filling rates and filling fractions. These methods are not easily applied to the study of large numbers of patients or serial assessment of individual patients. Doppler echocardiography is a noninvasive means of obtaining beat by beat analysis of LV diastolic filling.[6-10] The characteristics of the Doppler spectral display of diastolic transmitral flow velocity have been studied in patients with systemic hypertension, dilated cardiomyopathy, acute myocardial infarction and during percutaneous transluminal coronary angioplasty.[11-16] Rassi et al[17] have shown in normal subjects undergoing supine bicycle exercise that the mean mitral flow velocity increased by more than 100% from baseline to peak exercise. Changes in transmitral flow occurring with exercise in patients with coronary artery disease have not been well described. This study investigates the usefulness of Doppler assessment of LV diastolic function during stress testing in patients with known or suspected coronary artery disease as a possible marker of exercise-induced ischemia.

Methods

Patients: A total of 28 consecutive patients referred to the UCLA noninvasive cardiology laboratory for treadmill stress testing underwent simultaneous digi-

tal stress echocardiography and stress thallium imaging. The "ischemic" group (group 1) comprised 18 patients with exercise-induced wall-motion abnormalities, exercise-induced thallium perfusion defects, or both. The "nonischemic" group (group 2) included 10 patients without exercise-induced wall motion abnormalities and negative thallium scans. Since the time of initiation of stress echocardiography in this laboratory, a total of 10 patients undergoing digital stress echocardiography with measurement of transmitral flow velocity had normal results in their resting 12-lead electrocardiograms, resting and postexercise 2-dimensional echocardiograms and electrocardiographic treadmill stress testing. These patients, whose ages were similar to those of the study patients, constituted the control group (group 3).

Echocardiography: Resting and immediate postexercise 2-dimensional echocardiographic imaging was performed on supine subjects with a Hewlett-Packard 77020A echocardiographic recorder with a 2.5 MHz electronically phased array transducer with pulsed Doppler (2.0 MHz) capability. Optimal windows for obtaining parasternal and apical views at rest were clearly marked on each patient's chest wall. Immediate postexercise 2-dimensional echocardiographic images were obtained in all cases within 30 to 60 seconds of termination of upright treadmill exercise. Digitized cine loops of 2-dimensional echocardiographic images obtained using the apical 4-chamber, 2-chamber and long axis views and the parasternal short axis view were made on a Microsonics digitizing system. Each apical view was divided into 6 segments.[18] Wall-motion analysis was performed independently by 2 observers unaware of other patient data using a grading system from −1 for dyskinesia to 4 for hyperkinesia. Discrepancies between observers were resolved by consensus review. The development of a new exercise-induced wall-motion abnormality was defined as >1 grade deterioration in wall-motion score for any 1 segment from baseline to immediate postexercise. The development of dyskinesia in an area of prior akinesia was not considered a new wall-motion abnormality.

Doppler: The time-velocity profile of transmitral flow by pulsed Doppler was obtained with the sample volume placed on the ventricular side of the mitral anulus near the tips of the mitral leaflets. Beats used for analysis were those that showed the greatest mitral peak flow velocity regardless of the phase of respiration. Four parameters of LV filling were obtained from the analysis of the time-velocity spectral display: (1) peak velocity in early diastole; (2) peak velocity during atrial systole; (3) ratio of early diastolic peak flow velocity to peak flow velocity during atrial systole; (4) mean mitral flow velocity—obtained by digitizing the contour of the darkest outline of the spectral display of the transmitral time-velocity profile (Figure 1). Digitization was performed using a standard, commercially available, digitizing pad from Trinity Systems. The integrated area under the curve was expressed as the mean mitral flow velocity. The integrated area under the spectral envelope (mean mitral flow velocity) normalized for the diastolic filling period was expressed as the time-velocity integral. Pulsed Doppler measurements were obtained immediately after 2-dimensional echocardiographic imaging at baseline and upright treadmill exercise.

Thallium imaging: Stress thallium imaging was performed after obtaining echocardiographic studies immediately after exercise. Thallium images (64 of 20) were obtained using a Siemens Orbiter—SPECT system CLC 7500S. Redistribution images were obtained 4 hours after exercise. Those thallium perfusion defects present immediately after exercise and exhibiting redistribution 4 hours later were considered to represent exercise-induced myocardial ischemia. Thallium studies were read by consensus of 2 observers blinded to other patient data.

Statistical methods: Independent sample 2-tailed Wilcoxon rank sum tests for unpaired data were performed. Differences between means of more than 2 groups were evaluated by 1-way analysis of variance. 2 × 2 contingency tables were analyzed using the 2-tailed Fisher's exact test. Values are reported as mean ± standard deviation. A probability value <0.05 was considered to be significant.

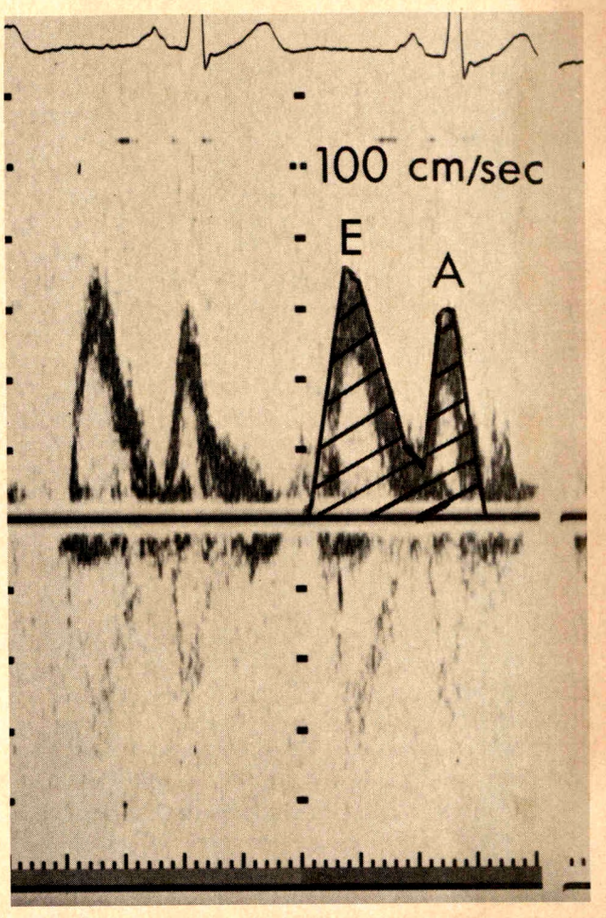

FIGURE 1. Sample spectral display of Doppler transmitral flow velocity. E = peak velocity in early diastole; A = peak velocity during atrial systole; integrated area under the darkest outline of the spectral display = mean mitral flow velocity.

Results

A summary of the overall results of simultaneous digital stress echocardiography and stress thallium imaging performed in the 28 consecutive patients with known or suspected coronary artery disease undergoing treadmill stress testing is shown in Figure 2. The 18 patients constituting the "ischemic group" (group 1) comprised 12 with positive SPECT thallium scan results (group 1A) and 6 with negative thallium scan findings but with exercise-induced wall-motion abnormalities (group 1B). Of the 10 patients with "nonischemic" studies (group 2), 7 had resting wall-motion abnormalities (Group 2A). For the 3 groups undergoing comparison, their mean ages (63 ± 10, 55 ± 12 and 55 ± 14 years for groups 1, 2 and 3, respectively), baseline heart rates (69 ± 18, 67 ± 12 and 61 ± 9 beats/min), postexercise heart rates (88 ± 23, 98 ± 20 and 91 ± beats/min), percentage of maximum predicted heart rates at peak exercise (81 ± 15, 87 ± 13 and 88 ± 12%), and double-products achieved (21,000 ± 5,000, 25,000 ± 7,000 and 25,000 ± 6,000 mm Hg · beats/min) were comparable. The number of patients in each group with a history of hypertension (8 of 18 in group 1, 3 of 10 in group 2 and 3 of 10 in group 3) was similar ($p = 0.9$). There was a trend toward greater use of calcium antagonists or β-blocking drugs in groups 1 and 2 (9 of 18 and 6 of 10, respectively), compared with group 3 (2 of 10) ($p = 0.2$).

Mean mitral flow velocities at baseline and after exercise for each of the patient groups are listed in Table I. In controls, the mean mitral flow velocity doubled, whereas patients with exercise-induced ischemia had an increase in mean mitral flow velocity of only 33% ($p < 0.005$). Sample Doppler tracings in a control and in an ischemic patient are shown in Figure 3. There was no difference between controls and patients with nonischemic studies despite the fact that 70% of the nonischemic patients had resting wall-motion abnormalities. There was no difference in the response of the mean mitral flow velocity with exercise between the group with positive thallium scan results and the group with exercise-induced wall-motion abnormalities and negative thallium scan results.

An increase in mean mitral flow velocity of >50% with exercise correctly identified 9 of 10 controls as nonischemic. The absence of a >50% increase in mean mitral flow velocity predicted an ischemic response in 15 of 18 patients with exercise-induced ischemia ($p < 0.005$). The number of patients demonstrating the proposed control response among those with nonischemic studies was similar to that among controls.

The time-velocity integral was obtained by dividing each mean mitral flow velocity by the diastolic filing period (duration of total transmitral flow). Baseline, postexercise and percent change in time-velocity integrals and diastolic filling periods for the 3 patient

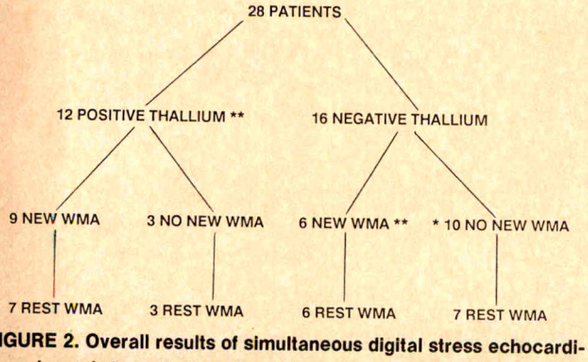

FIGURE 2. Overall results of simultaneous digital stress echocardiography and stress thallium imaging in 28 consecutive patients with known or suspected coronary after coronary artery disease. * nonischemic group; ** ischemic group. WMA = wall-motion abnormality.

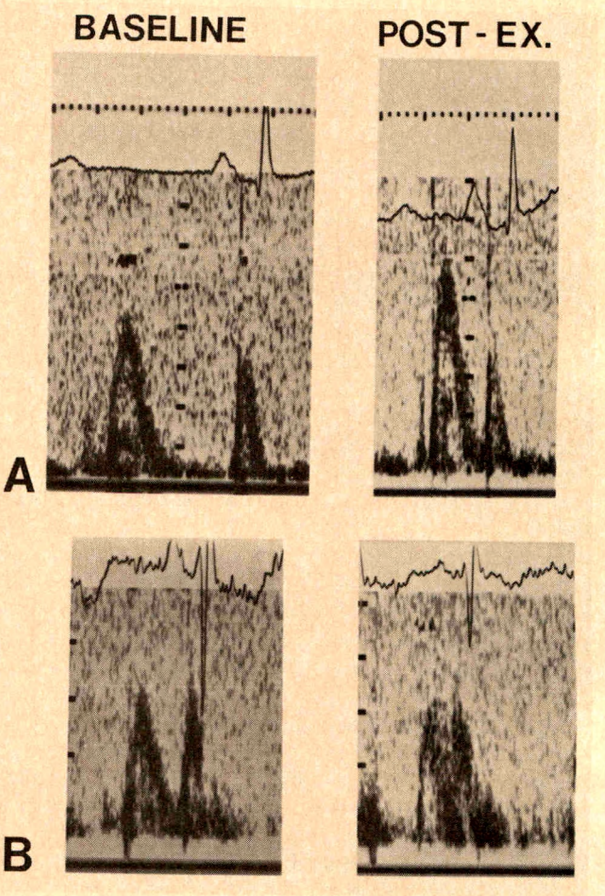

FIGURE 3. Preexercise and postexercise spectral display of Doppler transmitral flow velocity in 2 representative patients. *A*, control: a 61-year-old female, 13-minute total exercise time on Bruce protocol, reached 88% maximal predicted heart rate, double-product = 23,800, baseline mean mitral flow velocity = 33 cm/s, postexercise mean mitral flow velocity = 67 cm/s (103% increase). *B*, thallium redistribution and exercise wall-motion abnormality developed in this 58-year-old male, 11.5-minute total exercise time on Bruce protocol, reached 100% maximal predicted heart rate, double-product = 27,200, baseline mean mitral flow velocity = 42 cm/s, postexercise mean mitral flow velocity = 53 cm/s (26% increase). Each division = 20 cm/s.

TABLE I Mitral Flow Velocity Data

Pt Group	Baseline Mitral Flow Velocity (cm/s)	Postexercise Mitral Flow Velocity (cm/s)	Percent Change in Mitral Flow Velocity* (cm/s)	Patients with >50% Increase in Mitral Flow Velocity* (cm/s)
1	39 ± 13	51 ± 18	33 ± 24	3/18
1A	42 ± 15	56 ± 20	31 ± 29	2/12
1B	32 ± 6	41 ± 9	34 ± 24	1/6
2	33 ± 7	59 ± 12	86 ± 53	8/10
2A	35 ± 7	63 ± 10	90 ± 64	5/7
3	31 ± 7	60 ± 12	101 ± 59	9/10

All values are mean ± standard deviation.
* p = <0.005 between groups.

TABLE II Diastolic Filling Period and Time-Velocity Integral Data

Pt Group	Baseline DFP	Postexercise DFP	Percent Change in DFP	Baseline TVI	Postexercise TVI	Percent Change in TVI
1	0.48 ± 0.16	0.37 ± 0.15	23 ± 16	18 ± 5	17 ± 4	−1 ± 18
2	0.48 ± 0.11	0.29 ± 0.06	37 ± 14	16 ± 4	17 ± 4	13 ± 23
3	0.59 ± 0.13	0.34 ± 0.09	40 ± 18	17 ± 4	20 ± 4	11 ± 17
	NS	NS	p = 0.02	NS	NS	NS

All values are in mean ± standard deviation.
DFP = diastolic filling period (in seconds of diastole/beat); NS = not significant; TVI = time-velocity integral.

groups are listed in Table II. The percent change in time velocity integral from baseline to postexercise was no different among the 3 groups. The percent decrease in diastolic filling period was less for the ischemic group than either controls or patients with nonischemic studies (p = 0.02), despite similar heart rates at baseline and postexercise. The ratios of peak velocity in early diastole to peak velocity during atrial systole (E/A ratios), were no different among the patient groups at baseline or postexercise. The percent change in this parameter from baseline to postexercise did not differ among the 3 groups.

Discussion

Recent interest has focused on the use of Doppler velocity measurements to assess global LV function. Aortic and transmitral flow velocity determinations combined with anular cross-sectional area measurements have been used to attempt to estimate stroke volume and cardiac output.[19,20] The response of aortic flow velocity to exercise has been extensively studied.[21–23] Little is known of the response of transmitral flow to upright treadmill exercise in normal subjects or patients with coronary artery disease. This study corroborates the increase in transmitral flow velocity seen by Rassi et al[17] in normal subjects, by showing a similar increase of at least 100% in controls after treadmill exercise. It also demonstrates an abnormal response of the velocity of transmitral flow with exercise in patients with noninvasive evidence of stress-induced myocardial ischemia. The failure in ischemic patients to increase transmitral flow velocity with exercise to the extent seen in controls or nonischemic patients may be a reflection of ischemia-induced compromise of stroke volume, LV filling, or both. The change from baseline to postexercise in the time-velocity integral, which relates more directly to total transmitral flow than mean velocity alone, was not significantly different among the 3 study groups. Although given the small number of patients the likelihood of beta error must be considered, this would suggest that changes in stroke volume were not significantly different and that an abnormal response of mean mitral flow velocity with exercise in ischemic patients more likely represents an ischemia-induced change in LV compliance and, therefore, resistance to filling. Likewise, the smaller percent decrease in diastolic filling period from baseline to postexercise in ischemic patients may reflect a relative prolongation of the diastolic filling period due to ischemia-induced decrease in LV compliance.

The changes in the mean velocity of transmitral flow with exercise were similar in controls and patients without evidence of exercise-induced ischemia, even though 7 of 10 patients in this nonischemic group had resting wall-motion abnormalities on 2-dimensional echocardiography. When considered separately, these 7 patients with presumably nonischemic but infarcted hearts had quite similar increases in transmitral flow with exercise compared with controls. This would suggest that the abnormal response of transmitral flow velocity with exercise (i.e., failure to increase by at least 50%) may be a marker of exercise-induced ischemia rather than merely a marker of resting LV compliance abnormalities related to prior ischemic injury.

Because baseline, postexercise and percent of maximum predicted heart rates were all similar, the differences noted between groups in the response of mean mitral flow velocity to exercise are not a result of differences in heart rate. Likewise, the degree of stress induced was similar, as there was no difference between groups in double-product achieved. Changes in the pattern of LV filling by pulsed Doppler may occur with aging.[24-26] The control group used in this study was of an age distribution similar to the ischemic and nonischemic groups. Hypertension and therapy with calcium antagonists or β-blocking drugs can affect LV compliance. There was no significant difference between groups in the incidence of hypertension. Although there was a trend toward more frequent use of β-blockers or calcium antagonists in the ischemic and nonischemic groups, as compared with controls, this difference did not reach statistical significance. The effect of these agents on diastolic LV function would be to increase myocardial compliance, which would theoretically improve transmitral flow and, therefore, would not account for the differences shown. Regardless, each patient served as his or her own control for the comparison of rest versus immediate postexercise mitral flow velocities.

The peak velocity in early diastole (E) and peak velocity during atrial systole (A), obtained by pulsed Doppler, and their ratio (E/A ratio), have been studied in normal subjects and in various forms of acquired heart disease. The absolute values for the E/A ratio and the percent changes in E/A ratio from baseline to postexercise were no different between patient groups. With increased heart rates after exercise, it was noted that the E and A velocities tended to fuse, making separate determination of E and A velocity integrals technically difficult. The mean velocity of transmitral flow, which takes into account the velocities in early diastole and during atrial systole, would appear to be a more reliable and reproducible measure of Doppler-derived changes in transmitral flow with exercise.

The anyfingers patch.

All nitroglycerin patches work.

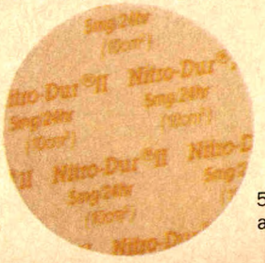
But Nitro-Dur II is the one nitroglycerin patch that works so readily, any fingers can easily open and apply it...even stiff fingers, clumsy fingers, arthritic fingers guided by presbyopic eyes.

Test it yourself. To see how easy handling Nitro-Dur II can be, open one and handle it yourself. Compare it with other patches.

Compare its thinness, its comfort, its appearance. Nitro-Dur II clings bulklessly and bulgelessly to the skin, so thin that pores and texture show through...so discreet about its presence that it's nearly invisible. Handle one and see. Handling is believing!

Nitro-Dur® II
(nitroglycerin)
Transdermal Infusion System

Easy to open... apply... remove.



5 mg patch, actual size.

Please see next page for brief summary of prescribing information.

Copyright © 1988, Key Pharmaceuticals, Inc., Kenilworth, NJ 07033. All rights reserved.

Nitro-Dur® II
(nitroglycerin)
Transdermal Infusion System

- **Easy opening**—even for arthritic hands.
- **Round-the-clock cling**—lies flat, holds tight.
- **Hard to notice, easy to wear**—semitransparent, soft and flexible.
- **Push-button removal**—just a press in the center raises the rim for easy lift-off.

When prescribing Nitro-Dur II, you should write your prescription using the Roman numeral designation II to identify the product. This should be followed by the appropriate dosage strength in mg/24 hours. Thus, any confusion that may arise between product names and/or dosage strengths prescribed will be avoided.

BRIEF SUMMARY

INDICATIONS AND USAGE: This drug product has been conditionally approved by the FDA for the prevention and treatment of angina pectoris due to coronary artery disease. The conditional approval reflects a determination that the drug may be marketed while further investigation of its effectiveness is undertaken. A final evaluation of the effectiveness of the product will be announced by the FDA.

CONTRAINDICATIONS: Intolerance of organic nitrate drugs, marked anemia.

WARNINGS: The NITRO-DUR II system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced or use of the product discontinued. NITRO-DUR II is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

Pregnancy: Pregnancy Category C. Animal reproduction studies have not been conducted with NITRO-DUR II. It is also not known whether nitroglycerin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Nitroglycerin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether nitroglycerin is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when NITRO-DUR II is administered to a nursing woman.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing NITRO-DUR II therapy. If headache persists, the NITRO-DUR II dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the NITRO-DUR II dosage should be reduced or use of the product discontinued.

CAUTION: Federal law prohibits dispensing without prescription. For complete prescribing information, please see package insert.

EDP #I030150 Revised 0585

All transdermal nitroglycerin products are being marketed pending final evaluation of effectiveness by the FDA.

CARDIOLOGIST, non-invasive, interested in general Internal Medicine, ICU care, echo, treadmill, holter, and rehab, to join another non-invasive Cardiologist in a 6 person Internal Medicine group in South Central Pennsylvania college town. Box 800, The American Journal of Cardiology, 249 W. 17th St., New York, N.Y. 10011.

CARDIOLOGIST—BC/BE experienced in electrophysiology to join existing busy group at large regional referral center. Modern hospital with two cardiac cath labs and active open heart surgical program. Excellent starting salary with early partnership. Reply Box 790, The American Journal of Cardiology, 249 W. 17th St., New York, N.Y. 10011.

ACADEMIC NONINVASIVE CARDIOLOGIST

The Likoff Cardiovascular Institute of Hahnemann University seeks a full time cardiologist interested in all aspects of Cardiac Ultrasound. Please contact Gary S. Mintz, M.D., Director, Cardiac Ultrasound Laboratory, Hahnemann University, 230 N. Broad Street, MS# 313, Philadelphia, PA 19102-1192.

CARDIOLOGIST—To join 5 FACC cardiologists in Northwestern PA. Consultative, invasive and non-invasive practice. Immediate opening. Reply Box 810, The American Journal of Cardiology, 249 W. 17th St., New York, N.Y. 10011.

CARDIOLOGIST—Immediate opening for two non-invasive BC/BE cardiologists to join two board certified invasive cardiologists in expanding group practice in mid-sized midwestern city. Expertise in echo, Doppler, nuclear cardiology desirable. Active cardiac surgery, angioplasty programs; practice includes office and hospital consultation, teaching opportunities if desired. Reply with CV to Box 735, The American Journal of Cardiology, 249 W. 17th St., New York, N.Y. 10011.

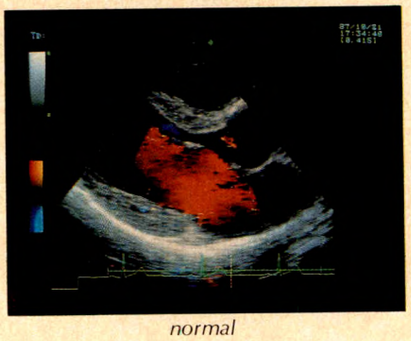
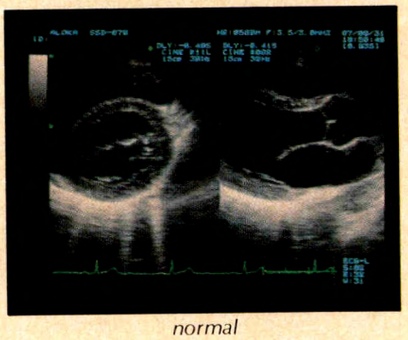
CATCH EVERY MOVE THEY MAKE ALOKA SSD-870 COLOR DOPPLER

Real-time two-dimensional ultrasound system for blood flow imaging with Cine Memory.



normal



normal

Imaging information can now be stored and retrieved in detail thanks to the new Cine Memory system in the Aloka SSD-870.

Then at your convenience, the study can be analyzed frame by frame to aid your diagnosis. Aloka's development of high performance imaging technology allows the dual 32-frame Cine Memory to display images with 60-frame-per-second accuracy. And multi-functional phased array transducers have been developed for the Aloka SSD-870.

Also high quality 2D, M mode, Conventional Pulsed and Continuous Doppler as well as Color Doppler studies are now possible through a single transducer. To learn more about the new Aloka SSD-870 Color Doppler system, please contact:

HYTRIN®

(terazosin hydrochloride tablets)

Brief Summary

CLINICAL PHARMACOLOGY: Pharmacodynamics: Clinical studies of terazosin used in once-a-day (majority) and b.i.d regimens with total doses usually in the range of 5-20mg/day, in patients with mild or moderate hypertension. Because terazosin, like all alpha antagonists, can cause large falls in blood pressure after the first dose or first few doses, the initial dose was 1mg in virtually all studies, with subsequent titration to a specified fixed dose or titration to a specified blood pressure end point.

Blood pressure responses were measured at the end of the dosing interval (usually 24 hrs.) and effects were shown to persist throughout the interval, with usual supine responses 5-10mmHg systolic and 3.5-8mmHg diastolic greater than placebo. The responses in the standing position tended to be somewhat larger, although this was not true in all studies. The magnitude of blood pressure responses was similar to prazosin and less than hydrochlorothiazide (in a single study). In measurements 24 hrs. after dosing, heart rate was unchanged.

Limited measurements of peak response (2-3 hrs. after dosing) during chronic terazosin administration indicate that it is more than twice the trough (24 hr.) response, suggesting some attenuation of response at 24 hrs., presumably due to a fall in blood terazosin concentrations at the end of the dose interval. This explanation is not established with certainty and is not consistent with the similarity of blood pressure response to once-a-day and b.i.d. dosing. With the absence of an observed dose-response relationship over a range of 5-20mg, i.e., if blood concentrations fall to the point of providing less than full effect at 24 hrs., a shorter dosing interval or larger dose should lead to increased response. Measure blood pressure (BP) at the end of the dose interval; if response is not satisfactory, patients may be tried on a larger dose or b.i.d. regimen. The latter should be considered if side effects, such as dizziness, palpitations, or orthostatic complaints, are seen within a few hours after dosing.

The greater BP effect associated with peak plasma concentrations (first few hours after dosing) appears somewhat more position-dependent (greater in the erect position) than the effect of terazosin at 24 hrs. In the erect position there is a 6-10 bpm increase in heart rate in the first few hours after dosing. During the first 3 hrs. after dosing 12.5% of patients had a systolic pressure fall of 30mmHg or more from supine to standing, or standing systolic pressure below 90mmHg with a fall of at least 20mmHg, compared to 4% of a placebo group.

INDICATIONS AND USAGE: Indicated for the treatment of hypertension.

CONTRAINDICATIONS: None known.

WARNINGS: Syncope and "First-dose" Effect: Terazosin, like other alpha-adrenergic blocking agents, can cause marked hypotension, especially postural hypotension, and syncope in association with the first dose or first few doses. A similar effect may occur if therapy is interrupted for more than a few doses. Syncope has been reported with other alpha-adrenergic blocking agents in association with rapid dosage increases or introduction of another antihypertensive drug. Syncope may be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by severe supraventricular tachycardia with heart rates of 120-160 bpm.

To decrease the likelihood of syncope or excessive hypotension, always initiate treatment with a 1mg dose at bedtime. The 2mg and 5mg tablets are not indicated as initial therapy. Increase dosage slowly, and add additional antihypertensive agents with caution. Caution patients to avoid situations where injury could result if syncope occurs during initiation of therapy.

In early studies, where increasing single doses up to 7.5mg were given at 3 day intervals, tolerance to the first dose phenomenon did not necessarily develop and the "first dose" effect was observed at all doses. Syncopal episodes occurred in 3 of 14 subjects given doses of 2.5, 5, and 7.5mg, which are higher than the recommended initial dose. Severe orthostatic hypotension (BP 50/0mmHg) was seen in two others and dizziness, tachycardia, and lightheadedness occurred in most subjects. These adverse effects all occurred within 90 min. of dosing.

In multiple dose clinical trials involving nearly 2000 patients, syncope was reported in about 1% of patients, in no case severe or prolonged, and was not necessarily associated with early doses.

If syncope occurs, place patient in recumbent position and treat supportively. There is evidence that the orthostatic effect of terazosin is greater, even in chronic use, shortly after dosing.

PRECAUTIONS: *General: **Orthostatic Hypotension:*** While syncope is the most severe orthostatic effect of terazosin, other symptoms of lowered BP, such as dizziness, lightheadedness and palpitations, are more common, occurring in 28% of patients in clinical trials. Patients with occupations in which such events represent potential problems should be treated with particular caution.

Information for Patients: Make aware of possibility of syncopal and orthostatic symptoms, especially at initiation of therapy, and to avoid driving or hazardous tasks for 12 hrs. after the first dose, after a dosage increase, and after interruption of therapy when treatment is resumed. Caution to avoid situations where injury could result should syncope occur during initial therapy. Advise to sit or lie down when symptoms of lowered BP occur and to rise carefully from a sitting or lying position. Bothersome dizziness, lightheadedness, or palpitations should be reported to physician.

Tell patients that drowsiness or somnolence can occur, requiring caution in people who must drive or operate heavy machinery.

Laboratory Tests: Small but statistically significant decreases in hematocrit, hemoglobin, WBC, total protein and albumin were observed in clinical trials. The magnitude of decreases did not worsen with time. These findings suggest the possibility of hemodilution.

Drug Interactions: In controlled trials, terazosin was added to diuretics, and several beta-adrenergic blockers; no unexpected interactions were observed. Terazosin has also been used concomitantly without interaction in at least 50 patients on the following: 1) analgesic/anti-inflammatory (acetaminophen, aspirin, codeine, ibuprofen, indomethacin); 2) antibiotics (erythromycin, trimethoprim and sulfamethoxazole); 3) anticholinergic/sympathomimetics (phenylephrine HCl, phenylpropanolamine HCl, pseudoephedrine HCl); 4) antigout (allopurinol); 5) antihistamines (chlorpheniramine); 6) cardiovascular agents (atenolol, hydrochlorothiazide, methyclothiazide, propranolol); 7) corticosteroids; 8) gastrointestinal agents (antacids); 9) hypoglycemics; 10) sedatives and tranquilizers (diazepam).

Carcinogenesis, Mutagenesis, Impairment of Fertility: HYTRIN was devoid of mutagenic potential when evaluated *in vivo* and *in vitro*.

HYTRIN, administered in feed to rats at doses of 8, 40, and 250mg/kg/day for 2 yrs., was associated with a statistically significant increase in benign adrenal medullary tumors of male rats exposed to the 250mg/kg dose. This dose is 695 X max. recommended human dose (20mg/55kg). Female rats were unaffected. HYTRIN was not oncogenic in mice when administered in feed for 2 yrs. at a maximum tolerated dose of 32mg/kg/day.

The absence of mutagenicity in a battery of tests, of tumorigenicity of any cell type in the mouse carcinogenicity assay, of increased total tumor incidence in either species, and of proliferative adrenal lesions in female rats, suggests a male rat species-specific event. Numerous other diverse pharmacological and chemical compounds have been associated with these tumors in male rats without supporting evidence for carcinogenicity in man.

Effects on fertility were assessed in a standard fertility/reproductive performance study in which male and female rats were administered oral doses of 8, 30 and 120mg/kg/day. Four of 20 male rats given 30mg/kg and 5 of 19 male rats given 120mg/kg failed to sire a litter. Testicular weights and morphology were unaffected. Vaginal smears at 30 and 120mg/kg/day appeared to contain less sperm than smears from control matings and good correlation was reported between sperm count and subsequent pregnancy.

Oral use for 1 or 2 yrs. elicited a statistically significant increase in testicular atrophy in rats exposed to 40 and 250mg/kg/day, but not in rats exposed to 8mg/kg/day (> 20 X max. recommended human dose). Testicular atrophy was observed in dogs dosed with 300mg/kg/day (> 800 X max. recommended human dose) for 3 months but not after 1 yr. when dosed with 20mg/kg/day. This lesion has also been seen with Minipress®.

Pregnancy: Teratogenic effects: Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women and the safety of terazosin in pregnancy has not been established. HYTRIN is not recommended during pregnancy unless potential benefit justifies potential risk to mother and fetus.

Nonteratogenic effects: In a peri- and post-natal development study in rats, significantly more pups died in the group dosed with 120mg/kg/day (> 300 X max. recommended human dose) than in the control group during the 3-week post-partum period.

Nursing Mothers: It is not known whether terazosin is excreted in breast milk; therefore, exercise caution when administering terazosin to a nursing woman.

Pediatric Use: Safety and effectiveness have not been determined.

ADVERSE REACTIONS: The prevalence of adverse reactions has been ascertained from 14 placebo-controlled studies conducted primarily in the U.S. The studies involved once-a-day administration of terazosin as monotherapy or in combination with other antihypertensive agents, at doses ranging from 1 to 40mg. All adverse events reported during these studies were recorded as adverse reactions. Adverse events where the prevalence rate in the terazosin group was at least 5%, where the prevalence rate for the terazosin group was at least 2% and was greater than the prevalence rate for the placebo group, or where the reaction is of particular interest are summarized below. Only asthenia, blurred vision, dizziness, nasal congestion, nausea, peripheral edema, palpitations and somnolence were significantly ($p < 0.05$) more common in patients receiving terazosin than in patients receiving placebo. Other events include **[%TERAZOSIN-%PLACEBO]**: asthenia (11.3%-4.3%), back pain (2.4%-1.2%), blurred vision (1.6%-0%), depression (0.3%-0.2%), dizziness (19.3%-7.5%), dyspnea (3.1%-2.4%), edema (0.9%-0.6%), headache (16.2%-15.8%), impotence (1.2%-1.4%), libido decreased (0.6%-0.2%), nasal congestion (5.9%-3.4%), nausea (4.4%-1.4%), nervousness (2.3%-1.8%), pain-extremities (3.5%-3%), palpitations (4.3%-1.2%), paresthesia (2.9%-1.4%), peripheral edema (5.5%-2.4%), postural hypotension (1.3%-0.4%), sinusitis (2.6%-1.4%), somnolence (5.4%-2.6%), tachycardia (1.9%-1.2%), weight gain (0.5%-0.2%).

Adverse reactions were usually mild or moderate in intensity but sometimes were serious enough to interrupt treatment. Adverse reactions that were most bothersome as judged by being reported as reasons for discontinuation of therapy by at least 0.5% of the terazosin group and being reported more often than in the placebo group **[%TERAZOSIN-%PLACEBO]** are: asthenia (1.6%-0%), blurred vision (0.6%-0%), dizziness (3.1%-0.4%), dyspnea (0.9%-0.6%), headache (1.3%-1%), nasal congestion (0.6%-0%), nausea (0.8%-0%), palpitations (1.4%-0.2%), paresthesia (0.8%-0.2%), peripheral edema (0.6%-0%), postural hypotension (0.5%-0%), somnolence (0.6%-0.2%), syncope (0.5%-0.2%), tachycardia (0.6%-0%).

Additional adverse reactions have been reported, but these are not distinguishable from symptoms that might have occurred in the absence of exposure to terazosin. The following additional adverse reactions were reported by at least 1% of 1987 patients who received terazosin in clinical studies or during marketing experience: abdominal pain, abnormal vision, anxiety, arrhythmia, arthralgia, arthritis, bronchitis, chest pain, cold symptoms, conjunctivitis, constipation, diarrhea, dry mouth, dyspepsia, epistaxis, facial edema, fever, flatulence, flu symptoms, gout, increased cough, insomnia, joint disorder, myalgia, neck pain, pharyngitis, pruritus, rash, rhinitis, shoulder pain, sweating, tinnitus, urinary frequency, urinary tract infection, vasodilation, vomiting.

DOSAGE AND ADMINISTRATION: Dose and dose interval (12 or 24 hrs.) should be adjusted according to BP response.

Initial Dose: 1mg at bedtime. Observe the initial dosing regimen strictly to minimize potential for severe hypotensive effects.

Subsequent Doses: Slowly increase dose to achieve desired BP response. Usual dose range is 1mg to 5mg once a day. Some patients may benefit from doses up to 20mg/day. Doses over 20mg do not appear to provide further BP effect. Doses over 40mg have not been studied. Monitor BP at the end of dosing interval to assure control is maintained. It may be helpful to measure BP 2-3 hrs. after dosing to see if maximum and minimum responses are similar, and to evaluate symptoms which can result from excessive hypotensive response. If response is substantially diminished at 24 hrs. consider an increased dose or b.i.d. regimen. **If administration is discontinued for several days or longer, reinstitute therapy using initial dosing regimen.** In clinical trials, except for the initial dose, the dose was given in the morning.

Use With Other Drugs: Caution should be observed when terazosin is administered concomitantly with other antihypertensive agents (e.g., calcium antagonists) to avoid the possibility of significant hypotension. When adding a diuretic or other antihypertensive agent, dosage reduction and retitration may be necessary.

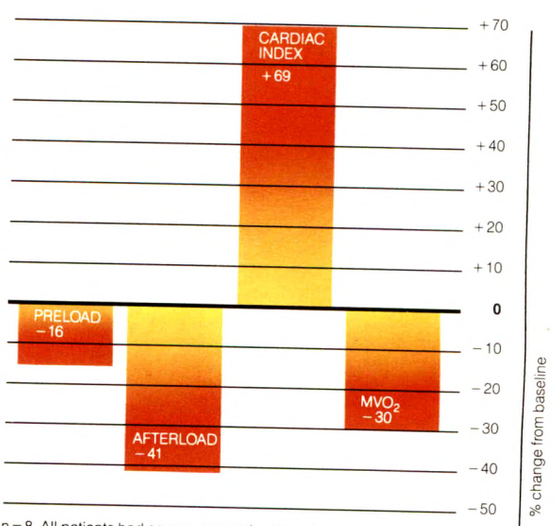
Dual action INOCOR® I.V. (AMRINONE) Inotropic plus vasodilating action in a single drug.

INOCOR I.V. rapidly helps achieve major goals of congestive heart failure therapy even in the ischemic patient.

INOCOR I.V. increases cardiac output and decreases preload and afterload without increasing MVO_2 or significantly increasing the risk of arrhythmias.

*"INOCOR is not like catecholamines....with INOCOR the pump works better without tachycardia and...without raising MVO_2."**

Karl T. Weber, M.D.
University of Chicago School of Medicine
Michael Reese Hospital and Medical Center



n = 8. All patients had severe congestive heart failure due to coronary artery disease. Amrinone was infused at 2.5 mg/kg over 1 hour. Adapted from Benotti et al.[1]

State-of-the-heart

Inocor® I.V.
(AMRINONE)

Dual-acting therapy,
instead of catecholamines

State-of-the-heart therapy.

(Brief Summary—see next page)

INOCOR I.V.

Two-in-one dual inotropic and vasodilator action provides improved therapy for the patient with acute heart failure.

■ Unlike catecholamines, INOCOR does not increase MVO_2 and can be used in ischemic patients with heart failure.

■ Unlike catecholamines, INOCOR does not significantly increase risk of arrhythmias (see Precautions).

Please consult full product information before prescribing. A summary follows.

INOCOR lactate injection, brand of amrinone lactate, represents a new class of cardiac inotropic agents with vasodilator activity, distinct from digitalis glycosides or catecholamines.

INDICATIONS AND USAGE (INOCOR lactate injection is indicated for the short-term management of congestive heart failure in patients who can be closely monitored and who have not responded adequately to digitalis, diuretics, and/or vasodilators.)

INOCOR lactate injection is indicated for the short-term management of congestive heart failure. Because of limited experience and potential for serious adverse effects (see ADVERSE REACTIONS), INOCOR should be used only in patients who can be closely monitored and who have not responded adequately to digitalis, diuretics, and/or vasodilators. Although most patients have been studied hemodynamically for periods only up to 24 hours, some patients were studied for longer periods and demonstrated consistent hemodynamic and clinical effects. The duration of therapy should depend on patient responsiveness.

CONTRAINDICATIONS INOCOR lactate injection is contraindicated in patients who are hypersensitive to it.

It is also contraindicated in those patients known to be hypersensitive to bisulfites.

PRECAUTIONS *General:* INOCOR lactate injection should not be used in patients with severe aortic or pulmonic valvular disease in lieu of surgical relief of the obstruction. Like other inotropic agents, it may aggravate outflow tract obstruction in hypertrophic subaortic stenosis.

During intravenous therapy with INOCOR lactate injection, blood pressure and heart rate should be monitored and the rate of infusion slowed or stopped in patients showing excessive decreases in blood pressure.

Patients who have received vigorous diuretic therapy may have insufficient cardiac filling pressure to respond adequately to INOCOR lactate injection, in which case cautious liberalization of fluid and electrolyte intake may be indicated.

Supraventricular and ventricular arrhythmias have been observed in the very high-risk population treated. While amrinone per se has not been shown to be arrhythmogenic, the potential for arrhythmia, present in congestive heart failure itself, may be increased by any drug or combination of drugs.

Thrombocytopenia and hepatotoxicity have been noted (see ADVERSE REACTIONS).

LABORATORY TESTS *Fluid and electrolytes:* Fluid and electrolyte changes and renal function should be carefully monitored during amrinone lactate therapy. Improvement in cardiac output with resultant diuresis may necessitate a reduction in the dose of diuretic. Potassium loss due to excessive diuresis may predispose digitalized patients to arrhythmias. Therefore, hypokalemia should be corrected by potassium supplementation in advance of or during amrinone use.

DRUG INTERACTIONS In a relatively limited experience, no untoward clinical manifestations have been observed in patients in whom INOCOR lactate injection was used concurrently with the following drugs: digitalis glycosides, lidocaine, quinidine, metoprolol, propranolol; hydralazine, prazosin, isosorbide dinitrate, nitroglycerine; chlorthalidone, ethacrynic acid, furosemide, hydrochlorothiazide, spironolactone, captopril, heparin, warfarin, potassium supplements, insulin, diazepam.

One case of excessive hypotension was reported when amrinone was used concurrently with disopyramide.

Until additional experience is available, concurrent administration with Norpace® disopyramide should be undertaken with caution.

USE IN ACUTE MYOCARDIAL INFARCTION INOCOR is not recommended for use in acute myocardial infarction.

USE IN CHILDREN Safety and effectiveness in children have not been established.

USE IN PREGNANCY *Pregnancy category C.* In New Zealand white rabbits, amrinone has been shown to produce fetal skeletal and gross external malformations at oral doses of 16 mg/kg and 50 mg/kg that were toxic for the rabbit. Studies in French Hy/Cr rabbits using oral doses up to 32 mg/kg/day did not confirm this finding. No malformations were seen in rats receiving amrinone intravenously at the maximum dose used, 15 mg/kg/day (approximately the recommended daily IV dose for patients with congestive heart failure). There are no adequate and well-controlled studies in pregnant women. Amrinone should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

USE IN NURSING MOTHERS Caution should be exercised when amrinone is administered to nursing women, since it is not known whether it is excreted in human milk.

ADVERSE REACTIONS *Thrombocytopenia:* Intravenous INOCOR lactate injection resulted in platelet count reductions to below 100,000/mm^3 in 2.4% of patients.

Gastrointestinal effects: Gastrointestinal adverse reactions reported with INOCOR lactate injection during clinical use included nausea (1.7%), vomiting (0.9%), abdominal pain (0.4%), and anorexia (0.4%).

Cardiovascular effects: Cardiovascular adverse reactions reported with INOCOR lactate injection include arrhythmia (3%) and hypotension (1.3%).

Hepatic toxicity: In dogs, at IV doses between 9 mg/kg/day and 32 mg/kg/day, amrinone showed dose-related hepatotoxicity manifested either as enzyme elevation or hepatic cell necrosis or both. Hepatotoxicity has been observed in man following long-term oral dosing and has been observed, in a limited experience (0.2%), following IV administration of amrinone.

Hypersensitivity: There have been reports of several apparent hypersensitivity reactions in patients treated with oral amrinone for about two weeks. Signs and symptoms were variable but included pericarditis, pleuritis, and ascites (one case); myositis with interstitial shadowing on chest x-ray and elevated sedimentation rate (one case); and vasculitis with nodular pulmonary densities, hypoxemia, and jaundice (one case). The first patient died, not necessarily of the possible reaction, while the last two resolved with discontinuation of therapy. None of the cases were rechallenged, so attribution to amrinone is not certain, but possible hypersensitivity reactions should be considered in any patient maintained for a prolonged period on amrinone.

General: Additional adverse reactions observed in intravenous amrinone clinical studies include fever (0.9%), chest pain (0.2%), and burning at the site of injection (0.2%).

OVERDOSAGE Doses of INOCOR lactate injection may produce hypotension because of its vasodilator effect. If this occurs, amrinone administration should be reduced or discontinued. No specific antidote is known, but general measures for circulatory support should be taken.

MANAGEMENT OF ADVERSE REACTIONS *Platelet count reductions:* Asymptomatic platelet count reduction (to less than 150,000/mm^3) may be reversed within one week of a decrease in drug dosage. Further, with no change in drug dosage, the count may stabilize at lower than predrug levels without any clinical sequelae. Predrug platelet counts and frequent platelet counts during therapy are recommended to assist in decisions regarding dosage modifications.

Should a platelet count less than 150,000/mm^3 occur, the following actions may be considered:

- Maintain total daily dose unchanged, since in some cases counts have either stabilized or returned to pretreatment levels.
- Decrease total daily dose.
- Discontinue amrinone if, in the clinical judgment of the physician, risk exceeds the potential benefit.

Gastrointestinal side effects: While gastrointestinal side effects were seen infrequently with IV therapy, should severe or debilitating ones occur, the physician may wish to reduce dosage or discontinue the drug based on the usual benefit-to-risk considerations.

Hepatic toxicity: In clinical experience to date with IV administration, hepatotoxicity has rarely been observed. If acute marked alterations in liver enzymes occur together with clinical symptoms, suggesting an idiosyncratic hypersensitivity reaction, amrinone therapy should be promptly discontinued.

If less than marked enzyme alterations occur without clinical symptoms, these nonspecific changes should be evaluated on an individual basis. The clinician may wish to continue amrinone and reduce the dosage or discontinue the drug based on the usual benefit-to-risk considerations.

HOW SUPPLIED Ampuls of 20 mL sterile, clear yellow solution containing INOCOR 5 mg/mL, box of 5 (NDC 0024-0888-20). Each 1 mL contains INOCOR lactate equivalent to 5-mg base and 0.25 mg sodium metabisulfite in water for injection.

Dynamics of Early and Late Left Ventricular Filling Determined by Doppler Two-Dimensional Echocardiography During Percutaneous Transluminal Coronary Angioplasty

LEIGH K. BOWMAN, MBBS, FRACP, MICHAEL W. CLEMAN, MD, HENRY S. CABIN, MD, BARRY L. ZARET, MD, and C. CARL JAFFE, MD

To study the influence of ischemia on both early and late left ventricular filling, Doppler 2-dimensional echocardiography was used to measure filling parameters during percutaneous transluminal coronary angioplasty (PTCA) in 26 patients. Doppler recordings were taken immediately before balloon inflation and continuously during balloon inflation and deflation until 60 seconds into the recovery period. During PTCA of the left anterior descending artery (16 patients) there was a 35% decrease in early peak filling rate from 269 ± 88 to 169 ± 55 ml/s ($p < 0.0005$) by 60 seconds of balloon inflation. In patients undergoing PTCA of the left circumflex (4 patients) or dominant right coronary artery (6 patients), the early peak filling rate decreased 15% from 325 ± 126 to 284 ± 137 ml/s ($p < 0.005$). The decrease in early peak filling rate became evident at approximately 15 seconds after balloon inflation and fully recovered 20 seconds after balloon deflation. Rather than an expected increase in atrial stroke volume and a decrease in early to late filling ratio during coronary occlusion, there was a 28% decrease in atrial stroke volume during left anterior descending coronary artery PTCA and a 6% decrease during right coronary and circumflex PTCA. Because of the simultaneous decrease in both early and late ventricular filling, peak early to late filling ratio was only slightly altered during PTCA. There was an 83% increase in mean pulmonary artery wedge pressure during balloon inflation from 12 ± 5 to 20 ± 4 mm Hg. In 11 of these patients global systolic function was measured on subsequent inflations during PTCA using 2-dimensional echocardiography. Ejection fraction during left anterior descending PTCA decreased from 62 ± 6 to 35 ± 7% ($p < 0.0005$) and correlated highly with the mean percent decrease in early peak filling rate ($r = 0.95$). During acute ischemia there are marked abnormalities in both early and late left ventricular filling that are paralleled by a commensurate decrease in systolic function. There is also a decrease in atrial stroke volume during coronary occlusion that may be due to atrial pump failure induced by atrial afterload mismatch.

(Am J Cardiol 1988;61:541–545)

Doppler echocardiographically derived early to late filling ratio and early peak filling rate[1,2] have been used to measure left ventricular diastolic function in patients in the resting state. Few clinical investigations have measured Doppler echocardiographically derived filling parameters during rapid fluctuations in hemodynamic variables or have assessed the influence of altered loading conditions on the atrial contribution to LV filling. Percutaneous transluminal coronary angioplasty (PTCA) provides a unique opportunity to use 2-dimensional Doppler echocardiography to study the magnitude and time course of changes in early and late left ventricular (LV) filling during dynamically changing conditions of diastolic function.[3–7] We measured Doppler-derived early and late filling rates during ischemia induced by balloon inflation during PTCA and assessed the relation of these changes to systolic dysfunction and mean pulmonary artery wedge pressure during ischemia.

Methods

Patients: Twenty-six consecutive patients undergoing PTCA with normal regional wall motion in the area supplied by the artery were studied. Three patients had a history of prior infarction and regional wall motion abnormalities in areas remote to the artery undergoing PTCA (2 patients undergoing left anterior descending PTCA had inferior hypokinesis and 1 patient undergoing right coronary artery PTCA had anteroapical akinesis). The left anterior descending artery was dilated in 16 patients, the circumflex artery in 4 and dominant right coronary artery in 6. To study the influence of occlusion of different coronary beds, patients were prospectively divided into 2 groups: group I consisted of all patients undergoing left anterior descending artery PTCA and group II consisted of patients undergoing PTCA of the circumflex or right coronary artery. No patient had angiographically visible collaterals to the artery undergoing dilation. There were 22 men and 4 women, mean age 53 ± 9 years (range 44 to 70). Medications taken by the patients consisted of combined β blockers and calcium antagonists in 12 patients, calcium antagonists alone in 6 and β blockers alone in 3. Medications were not terminated before the procedure. Nitroglycerin and atropine were given to all patients when the procedure began. Informed consent using an institutionally approved form was obtained from all patients.

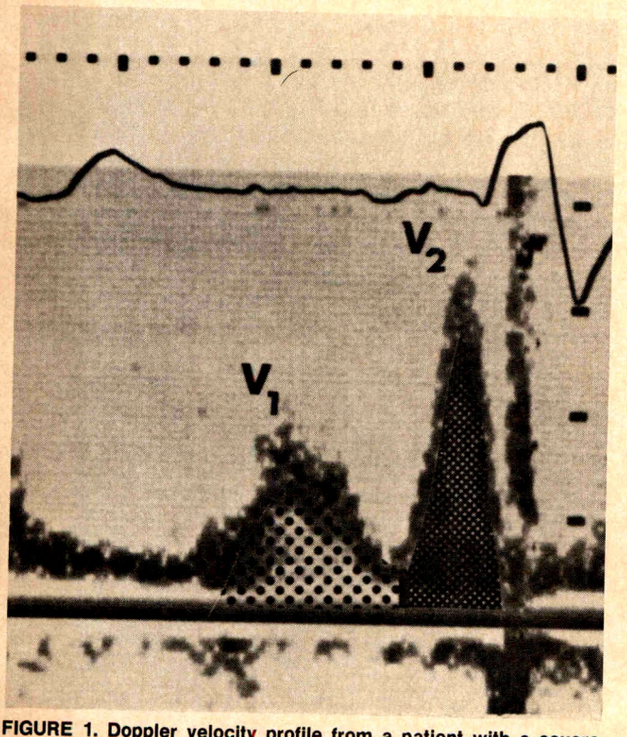

FIGURE 1. Doppler velocity profile from a patient with a severe proximal left anterior descending artery lesion and reduced early peak filling rate. V_1 = early peak filling velocity; V_2 = late peak filling velocity. The *dotted area* indicates the early filling integral and the *shaded area* indicates the late filling integral.

Angioplasty procedure: The PTCA was performed with USCI balloon dilatation catheter systems ranging in balloon diameter from 2.5 to 3.5 mm. The balloon inflation times were 60 seconds for all measured inflations. Multiple inflations were performed on each patient with balloon inflation pressures ranging from 6 to 11 atmospheres. At least 2 minutes was allowed between each inflation and return to baseline conditions was verified by examining the 2-dimensional and Doppler signals.

Doppler technique: A Hewlett Packard ultrasound machine (model 77020A) equipped with a 2.5-MHz pulsed Doppler transducer was used for the measurement of transmitral blood flow velocity. An apical 4-chamber view was obtained with the patient lying supine. The diameter of the mitral anulus was measured at the insertion of the anterior and posterior mitral leaflets as previously described.[8] The cross-sectional area of the mitral anulus was calculated assuming a circular shape. A sample volume (length 5 mm) was positioned just on the ventricular side of the mitral anulus and aligned so that the angle between the ultrasound beam and the blood flow vector was as close to zero as possible. Transmitral velocity waveform was recorded at 100 mm/s on half-inch VHS video tape. When the balloon inflation sequences were begun, ultrasonic recordings were obtained continuously from 30 seconds before inflation until 60 seconds after balloon deflation. The video tape record of the Doppler velocity profiles was analyzed by an off-line computer system. Five cardiac cycles were averaged immediately before balloon inflation. During balloon inflation, mitral inflow velocity profiles from individual cardiac cycles were observed continuously and quantitatively analyzed at the 60-second balloon inflation point. After verifying mitral anulus diameter constancy in the 11 of 26 patients in whom systolic function was assessed, mitral inflow profiles were analyzed assuming a fixed mitral anular cross-sectional area during balloon inflation.

Calculation of filling parameters: Early peak filling velocity was identified as the maximal deflection in the velocity profile before the onset of atrial contraction (Figure 1). Late peak filling velocity was defined as the maximum deflection after diastasis occurring in the second half of diastole. Early peak velocity was multiplied by the mitral anular cross-sectional area to derive early peak filling rate. The total area under the mitral inflow velocity curve was planimetered by following the most intense portion of the velocity curve to derive the time velocity integral of mitral inflow (cm), which was multipled by mitral anular cross-sectional area to derive stroke volume (in ml). The integral of the early phase of mitral filling (E integral) was defined as the area under the curve from the onset of filling until the onset of atrial flow velocity. The integral of late filling (A integral) was defined as the area under the curve from the onset of atrial flow velocity until the cessation of flow. The ratio of early peak filling velocity and late peak filling velocity was derived by dividing early peak velocity by the late peak filling velocity. The ratio of early and late filling

integrals was derived by dividing the early filling integral by the late filling integral.

Measurement of systolic function: In 11 patients within this same cohort, LV systolic function was assessed by 2-dimensional echocardiography on subsequent balloon inflations in the PTCA sequence for comparison with diastolic function—in 8 patients during left anterior descending artery PTCA, in 2 during circumflex PTCA and in 1 patient during right coronary artery PTCA. Previous studies from this institution have demonstrated complete recovery of systolic function after each balloon inflation thereby permitting comparison between systolic and diastolic function on consecutive inflations.[9,10] Systolic function could not be measured in the remaining patients due to some combination of the following factors: insufficient balloon inflations, fluoroscopy during inflations, concern regarding patient stability or difficulty in obtaining adequate 2-dimensional images without undue delay. An apical long-axis view of the left ventricle, in a plane selected to give the best view of the ischemic segment, was obtained. Recordings on half-inch VHS videotape were made from 30 seconds before balloon inflation until 60 seconds after balloon deflation and analyzed using an off-line computer system. End-systolic volume, end-diastolic volume and ejection fraction were calculated from digitized endocardial contours using an area length formula.[11,12]

Pulmonary artery wedge measurements during angioplasty: To assess the relation between mean pulmonary artery wedge pressure and ventricular filling dynamics, mean pulmonary artery wedge pressure measurements were taken at baseline and during 9 balloon inflations in 9 patients (left anterior descending artery in 7, right coronary artery PTCA in 2) via a 7Fr flow-directed pulmonary artery catheter. In 4 of these patients Doppler and wedge pressures were obtained simultaneously.

Statistics: Paired and unpaired Student's *t* tests were used to assess significant differences between groups. Mean and standard deviation of data groups are reported. Linear regression using a least squares method was used to assess comparisons between data groups.

Results

Hemodynamics: Baseline heart rate was 74 ± 10 beats/min and was 75 ± 11 (difference not significant) during balloon inflation. Heart rate after 60 seconds of recovery was 73 ± 11 beats/min. Mean baseline blood pressure was 128 ± 17/77 ± 12 and decreased to 118 ± 14/68 ± 9 mm Hg after the final balloon inflation. The mean number of balloon inflations performed per patient was 6.5 ± 4.0. The mean percent stenosis decreased from 92 ± 5 to 13 ± 10% and the mean gradient across the lesion decreased from 51 ± 10 to 10 ± 6 mm Hg. The mean number of inflations before recording of the ultrasonic data 1.6 ± 1.7. The mean mitral anulus diameter in the 11 patients who had 2-dimensional studies during PTCA was 2.77 ± 0.33 at baseline and 2.79 ± 0.29 cm after 60 seconds of balloon inflation (difference not significant).

Comparison of filling rates in group I and group II: *Early filling during angioplasty:* The effect of PTCA on filling dynamics is summarized in Tables I and II. In both groups there was a decrease in early peak filling rate and E integral that occurred 15 to 20 seconds after balloon inflation and continued to decrease until balloon deflation. In the left anterior descending coronary artery patients there was a 35% decrease in early peak filling rate from 269 ± 88 to 169 ± 55 ml/s ($p < 0.0005$) and a 44% decrease in E integral from 5.1 ± 1.5 to 2.9 ± 1.1 cm. In the group II patients there was only a 13% decrease in early filling from 6.5 ± 1.8 to 5.6 ± 2.2 cm. The magnitude of the decrease in early peak filling rate during balloon inflation was significantly higher in group I than in group II patients ($p < 0.001$). In both groups there was complete recovery of early peak and integral filling. Group I patients sustained a mean decrease in stroke volume of 36% from preinflation values compared with group II patients, who sustained a 14% decrease in stroke volume.

Atrial stroke volume during angioplasty: In both groups there was a decrease in the mean atrial contribution to LV filling during balloon inflation. This decrease was much more marked in the left anterior descending coronary artery group of patients who sustained a 28% decrease in late filling integral compared with a 6% decrease in group II patients. The decrease in the atrial contribution to ventricular filling in the left anterior descending coronary artery group of patients was associated with a concomitant decrease in early filling integral and early peak filling rate. Therefore, a relatively small change in peak and integral early to late filling ratios was observed during balloon inflation.

Mean pulmonary artery wedge pressure during angioplasty: The dynamic fluctuations in ventricular filling were associated with marked changes in pulmonary artery wedge pressure. In the 9 patients mean pulmonary artery wedge increased 83% from 12 ± 5 to 20 ± 4 mm Hg during balloon inflation. This was associated with a decrease in late filling from 31 ± 9 to 20 ± 8 ml. As demonstrated in 4 of the patients (Figure 2), late filling decreased during balloon inflation as mean pulmonary artery wedge pressure increased beyond 15 mm Hg.

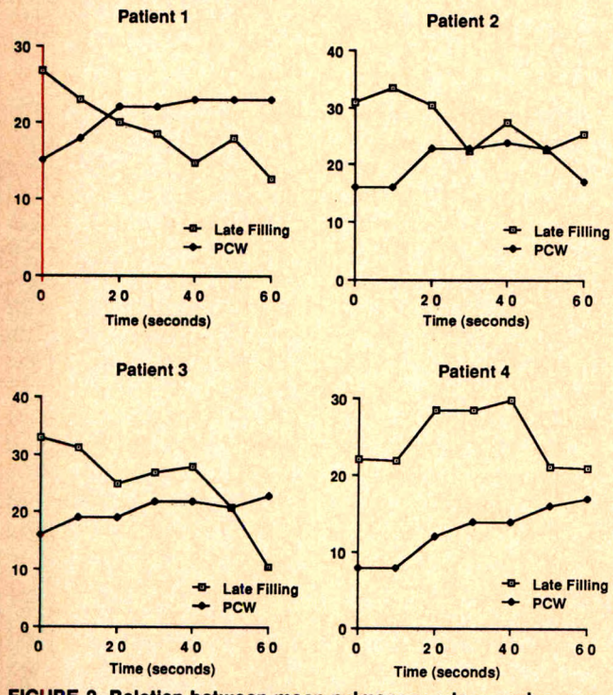

FIGURE 2. Relation between mean pulmonary artery wedge pressure (PCW) and late filling during angioplasty in 4 patients. The y axis units represent both mm Hg for mean pulmonary artery wedge pressure and ml for late filling. During balloon inflation, there is a marked decrease in late filling as pulmonary artery wedge pressure increases beyond 15 mm Hg.

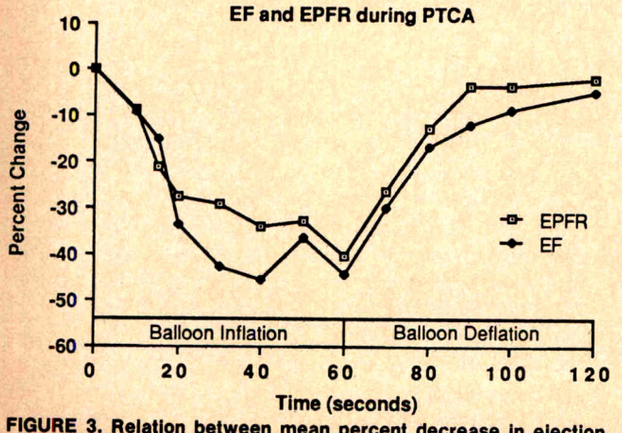

FIGURE 3. Relation between mean percent decrease in ejection fraction (EF) and mean early peak filling rate (EPFR) during balloon inflation in 11 patients undergoing left anterior descending artery angioplasty.

Relation between systolic function and early peak filling rate during angioplasty: There was a close relation between changes in systolic function and early LV filling during PTCA in both timing and magnitude. In the left anterior descending artery patients there was a decrease in mean ejection fraction from 62 ± 6 before inflation to 35 ± 6% at 60 seconds of inflation time ($p < 0.0005$) with recovery to 56 ± 8% at 30 seconds of recovery time (difference not significant compared with preinflation ejection fraction). In the 2 circumflex patients and 1 right coronary artery patient there was no significant change in ejection fraction from preinflation (66 ± 9%) to 60 seconds of inflation time (67 ± 8%). The time course and magnitude of percent change in ejection fraction compared with percent change in early peak filling rate is shown in Figure 3. In the left anterior descending artery group there was a near doubling of end systolic volume from 50 ± 20 immediately before inflation to 96 ± 34 ml at 60 seconds of inflation time ($p < 0.0001$) and a 21% increase in end-diastolic volume from 125 ± 46 to 148 ± 47 ml ($p < 0.05$). Recovery end-diastolic volume was 138 ± 40 ml (difference not significant compared with baseline).

Discussion

Previous studies[3,6,7,13] have induced ischemia by rapid atrial pacing and have measured ventriculographically derived pressure-volume curves and peak filling rates during PTCA. These investigations have demonstrated marked abnormalities of diastolic function during and after ischemia that may be caused by many factors, including increased regional myocardial stiffness,[3-5] delayed nonuniform relaxation[13-19] and alterations in right ventricular load.[16] In this study we demonstrated that Doppler-derived peak filling rate can detect marked changes in early peak filling occurring during ischemia. The baseline early peak filling rates in both groups are below the previously reported normal range of 503 ± 171 ml/s.[20] These data are consistent with previous reports of abnormal LV filling dynamics in patients with coronary artery disease.[21-22] During balloon inflation there were profound changes in LV filling dynamics. Early filling decreased within 15 to 20 seconds after the onset of balloon occlusion and completely recovered to baseline levels 20 seconds after balloon deflation. There was a mean decrease of 38% in early peak filling rate in the left anterior descending artery group but a decrease of only 14% in group II patients. This suggests that changes in early peak filling rate in the setting of acute ischemia are proportional to the amount of myocardium rendered ischemic. In association with the decrease in early filling rate during PTCA there was a concomitant decrease in global systolic function. In agreement with other studies,[23] we found that the onset of diastolic dysfunction during PTCA often preceded other measures of ischemia such as systolic function.

Late filling during angioplasty: We have demonstrated that late ventricular filling decreases during coronary occlusion particularly of the left anterior descending coronary artery. This decrease occurred at a time when there was also a marked decrease in early peak filling rate and thus the early to late filling ratio showed small change. One would have expected the early to late filling ratio to decrease during ischemia of the left ventricle as end-diastolic pressure increased and early peak filling rate decreased. This decrease in late ventricular filling during ischemia suggests that there is a limit to the compensatory increase in the atrial contribution to LV filling after increases in ventricular diastolic stiffness. This phenomenon may be explained by several factors. Severe ischemia causes both an increase in end diastolic volume[24] (20% in this study) and an upward shift in the pressure volume curve.[4] Both of these factors lead to marked increases in end-diastolic pressure and increased impedance to left atrial ejection. The thin walled atrium in the acute setting is presumably unable to eject as efficiently against this increased impedance, resulting in atrial afterload mismatch and atrial pump failure. Other studies provide supporting evidence for this concept. These dynamic fluctuations in late ventricular filling suggest that patients with severe abnormalities of diastolic function may develop atrial failure induced by high impedance to atrial ejection. This may explain preliminary reports demonstrating poor correlation between early to late filling ratios and invasive indexes of diastolic function.

Study limitations: The changes in diastolic function during PTCA noted in this study may not be fully applicable to changes seen in the setting of increased demand ischemia. Paulus et al[25] studied the differences between increased demand-induced ischemia and decreased supply-induced ischemia in dogs and found that pacing-induced ischemia induces an upward shift in the pressure volume relation as opposed to occlusive ischemia, which was associated with a downward shift in the diastolic pressure volume relation.

Early and Late Assessment of Stenosis Geometry After Coronary Arterial Stenting

JACQUES PUEL, MD, YVES JUILLIERE, MD, MICHEL E. BERTRAND, MD, ANTHONY F. RICKARDS, MD, ULRICH SIGWART, MD, and PATRICK W. SERRUYS, MD

Early and late modifications of stenosis geometry after stenting of coronary arteries were assessed. Morphologic changes were evaluated by quantitative coronary angiography (automated edge-detection) and theoretical pressure drop across the dilated and stented stenosis was calculated from the Poiseuille formula, with turbulent resistances assuming a coronary blood flow of 1 or 3 ml/s. Eleven patients (ages 41 to 69 years, mean 55) were studied before and after angioplasty, and immediately after stent implantation. The stented coronary artery was the left anterior descending artery in 9 patients and the left circumflex in 2. Following stent implantation, an additional increase in minimal luminal cross-sectional area of the dilated vessel was observed, suggesting that the self-expanding stainless-steel endoprosthesis used had a dilating function in addition to its stenting role. Repeat angiography in 6 patients 3 months after stent implantation showed a decrease in the minimal luminal cross-sectional area without a significant change in theoretic pressure decrease. This slight reduction in vessel caliber had no hemodynamically significant repercussions. Thus, stenting of coronary arteries following dilatation is a potentially valuable technique for preventing both abrupt closure and late reduction in lumen diameter.

(Am J Cardiol 1988;61:546–553)

Although other techniques—pharmacologic,[1] mechanical and thermal[2,3]—are currently under investigation, intravascular stenting of the dilated vessels has been proposed as an alternative approach for preventing late restenosis after percutaneous transluminal coronary angioplasty (PTCA). Different prostheses have been developed and tested in animal experiments[4–10] and, recently, intravascular stents have been implanted in patients.[11] The endoprosthesis used in this open clinical trial consists of a self-expanding stainless-steel mesh that exerts a radial force on the vascular wall. So far, there are no quantitative angiographic data indicating whether the endoluminal prosthesis affects the immediate anatomic result of PTCA. On the other hand, because animal experiments have shown a neointimal proliferation totally encasing stent wires within a few weeks,[8–10] it is crucial to demonstrate that the stenotic geometry of the human stented artery does not deteriorate at short-term follow-up.

This study assesses early and delayed modifications in stenotic geometry by quantitative coronary angiography after stenting of coronary arteries in 11 patients.

Study population: The 11 patients ranged in age from 41 to 69 years (mean 55) and 8 were men. They were treated and investigated in the 3 following centers: Department of Clinical and Experimental Cardiology, CHRU Rangueil, Toulouse, France (patients 6 - 11), Catheterization Laboratory, Thoraxcenter, Rotterdam, The Netherlands (patients 1-3) and Department of Cardiology, Hospital Cardiologique, Lille, France (patients 4-5). Informed consent was obtained from each patient before the intervention. The endoprosthesis used in this study was provided by Medinvent SA. The dilated and stented coronary artery was the left anterior descending artery in 9 patients and the left circumflex artery in 2. This series of 11 patients includ-

ed the first 6 consecutive patients who had an endoprosthesis implanted in Toulouse for secondary prevention of restenosis and the first 5 patients with implants for primary prevention of restenosis in the pilot phase of a multicenter trial (Coronary Artery Stent Implant Study [CASIS]). No coronary spasm occurred at the time of endoprosthesis implantation. In patient 7, a transient decrease from 3.1 to 2.5 mm in the reference diameter was observed immediately after the dilation and before stent implantation. This 0.6-mm change was greater than the average variability for this parameter and was therefore attributed to a diffuse spastic reaction. Among the 11 patients, 3 presented with an early thrombosis, 2 of them were successfully recanalized by thrombolytic therapy and PTCA; 6 were reinvestigated after a 3-month follow-up. The medications at the time of the initial and 3-month angiograms were identical and consisted of acetyl salicylic acid, dypiridamole, nitrates and calcium antagonists. The subcutaneous heparin was discontinued 6 weeks after the stent implantation. Repeat coronary angiography was performed 3 months after implantation in 6 patients (5 men, 1 woman).

Methods

Description of the stent[11]: The stent is woven from a surgical-grade stainless-steel alloy formulated according to the specifications of the International Standards Organization. The prosthesis is geometrically stable, pliable and self-expanding. Its elastic and pliable properties are such that the diameter can be substantially reduced by moderate elongation. The prosthesis can be constrained on a small-diameter delivery

catheter and, as the constraining membrane is progressively removed, the elastic device assumes its original (unconstrained) larger diameter. The constrained wire-mesh prosthesis is held at the distal end of the delivery catheter by a doubled-over membrane, the outer layer of which can be progressively withdrawn. Two radiopaque metal markers on the delivery catheter facilitate identification of the end of the prosthesis at the time of its deployment. The outer diameter of the loaded catheter system is 1.57 mm and prostheses able to expand to a diameter of 6.5 mm are mounted on this delivery device (Figure 1).

In this study, unconstrained stent diameter ranged from 3.0 to 3.5 mm. The selection of stent sizes depended upon the size of the arterial segment, taking into consideration that the stent in its unconstrained form must have a diameter 0.5 mm larger than the stented vessel. The prosthesis consisted of 16 wire filaments each 0.08-mm wide.

Quantitative coronary angiography: The determination of coronary arterial dimensions from 35-mm cinefilm was performed with the computer-based Cardiovascular Angiography Analysis System.[12-15] In essence, boundaries of the relevant coronary artery segment are detected automatically from optically magnified and video-digitized regions of interest of a selected cineframe. The absolute diameter of the stenosis (in mm) is determined using the guiding catheter as a scaling device. The detected contours of the arterial and catheter segments are corrected for pincushion distortion.[12,14] A computerized estimation of the original arterial dimension at the site of the obstruction is used to define the interpolated reference region.[12,13] The interpolated percentage area stenosis and the minimal luminal cross-sectional area (mm^2) are then calculated and averaged from, if possible, at least 2, preferably orthogonal projections. The length of the lesion is determined from the diameter function on the basis of a curvature analysis.

The variability in obstruction diameter for short- (5 min), medium- (60 min) and long-term (90 days) studies ranged from 0.22 mm for the short-term study to 0.36 mm for the long-term study.[13] In the long-term study group, the lack of significant variation in the mean difference of the minimal lumen diameters suggested that no detectable progression or regression of atherosclerotic lesions had occurred over the 90-day period. Therefore, a change greater than the total measurement variability of repeated coronary cineangiography and quantitative analysis (0.36 mm for obstruction diameter; i.e., 1 standard deviation of difference of duplicate measurements) was considered significant and indicative of restenosis.

Hemodynamic assessment: The theoretic pressure drop was calculated using the arteriogram and digital computation, according to well-known formulas described in the literature:[16-18] $Pgrad = Q \cdot (Rp + Q \cdot Rt)$ where Pgrad is the theoretic transstenotic pressure decrease (mm Hg) over the stenosis, Q the mean coronary blood flow (ml/s), Rp the Poiseuille resistance and Rt the turbulent resistance.

These resistances have been defined as follows:

$$Rp = C_1 \cdot (\text{length obstruction}) / (\text{minimal cross-sectional area})^2$$

where $C_1 = 8 \cdot \pi \cdot$ (blood viscosity) with blood viscosity = 0.03 g/cm · s.

$$Rt = C_2 (1/\text{minimal cross-sectional area} - 1/\text{normal distal area})^2$$

where C_2 = (blood density)/0.266 with blood density = 1.0 g/cm^3.

The theoretic transstenotic pressure drop was calculated for a theoretic coronary blood flow of 0.5, 1 and 3 ml/s. The Poiseuille and turbulent contributions to flow resistance were determined from stenotic geometry assessed by quantitative coronary angiography.

Statistical analysis: Comparisons between post-PTCA and post-stenting measurements and between post-stenting and 3-month follow-up measurements were carried out using the Student *t* test for paired observations.

Results

Early assessment immediately after stenting (Figure 2A-C): The 11 patients were studied and a mean of

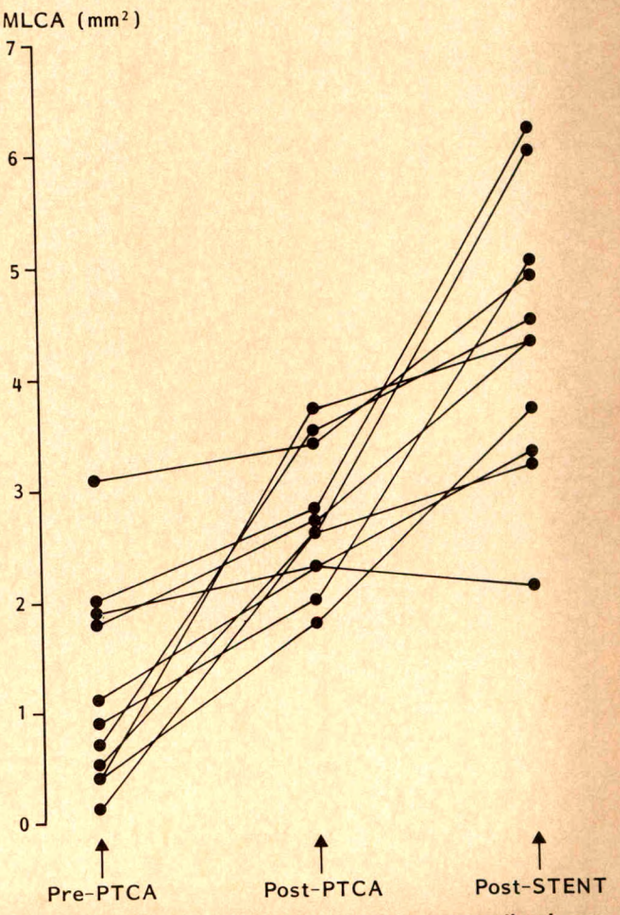

FIGURE 3. Changes in minimal luminal cross-sectional area (MLCA) between pre- (pre-PTCA) and post-angioplasty (post-PTCA), and immediately after stent implantation (post-STENT).

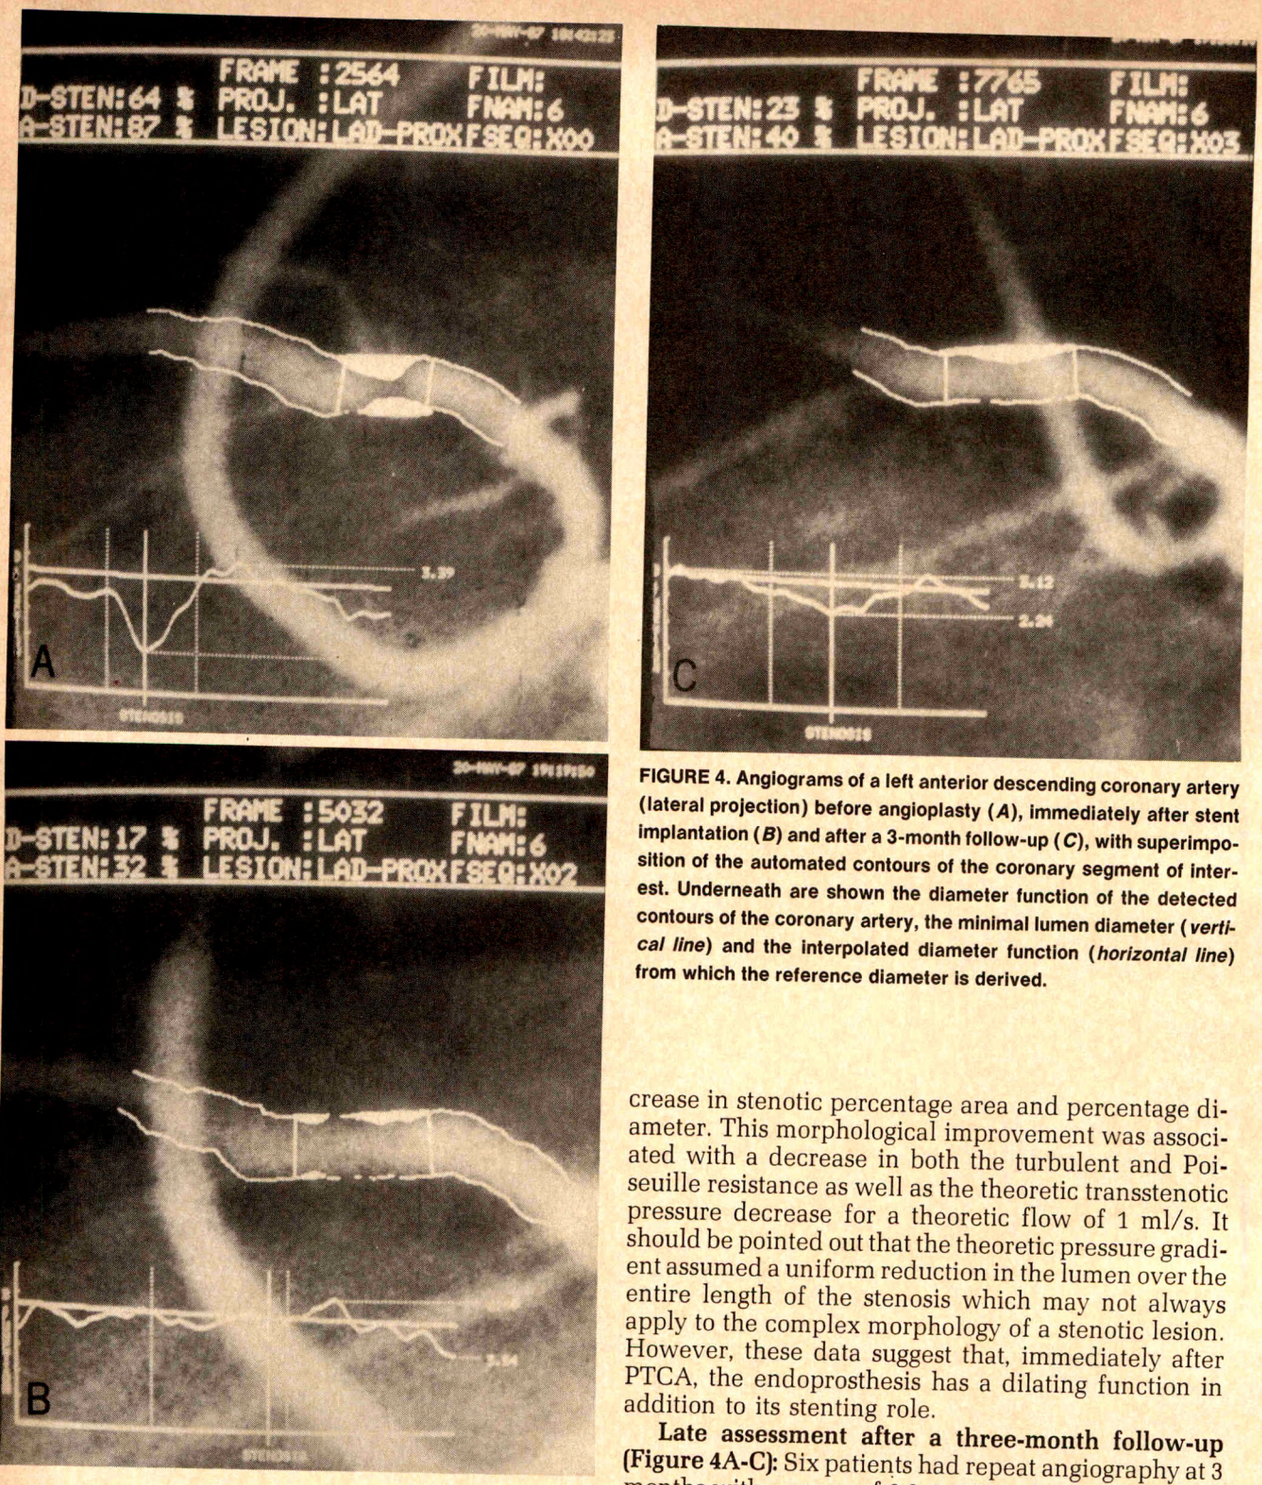

FIGURE 4. Angiograms of a left anterior descending coronary artery (lateral projection) before angioplasty (*A*), immediately after stent implantation (*B*) and after a 3-month follow-up (*C*), with superimposition of the automated contours of the coronary segment of interest. Underneath are shown the diameter function of the detected contours of the coronary artery, the minimal lumen diameter (*vertical line*) and the interpolated diameter function (*horizontal line*) from which the reference diameter is derived.

2.0 ± 0.4 angiographic projections per lesion was analyzed. The morphologic and hemodynamic data (mean ± standard error of the mean as well as the individual values of the parameters for each patient), are listed in Table I and II, respectively.

Stent implantation following PTCA resulted in an additional increase in minimal luminal cross-sectional area (Figure 3) and obstruction diameter, and a decrease in stenotic percentage area and percentage diameter. This morphological improvement was associated with a decrease in both the turbulent and Poiseuille resistance as well as the theoretic transstenotic pressure decrease for a theoretic flow of 1 ml/s. It should be pointed out that the theoretic pressure gradient assumed a uniform reduction in the lumen over the entire length of the stenosis which may not always apply to the complex morphology of a stenotic lesion. However, these data suggest that, immediately after PTCA, the endoprosthesis has a dilating function in addition to its stenting role.

Late assessment after a three-month follow-up (Figure 4A-C): Six patients had repeat angiography at 3 months with a mean of 2.0 ± 0.2 angiographic projections per lesion. The morphologic and hemodynamic data (mean ± standard error or the mean, as well as the individual values of the parameters for each patient) are listed in Table I and II, respectively.

The 3-month follow-up revealed a decrease in minimal luminal cross-sectional area (Figure 5), a decrease in obstruction diameter and an increase in stenotic percentage area and percentage diameter, when compared with the values recorded immediately after stent implantation. The obstruction diameter de-

creased from 2.4 ± 0.1 mm to 2.0 ± 0.1 mm and the stenotic percentage diameter increased from 23 ± 4% to 34 ± 3%. The reduction in obstruction diameter was probably due to the neointimal proliferation, which theoretically should result in a diameter reduction of 0.2 mm. The turbulent and Poiseuille resistance also increased significantly, but such an increase did not result in a hemodynamically significant pressure decrease over the stent for theoretic flow rates of 1 to 3 ml/s.

Discussion

A promising new approach to reduce the rate of restenosis is the implantation of an intravascular endoprosthesis. The principle of introducing intraarterial grafts percutaneously was first described by Dotter in 1969.[5] During the last few years, variants of the original technique using thermal-shaped memory alloys,[4-19] expanding spring steel spirals,[6] expanding stainless-steel stents[10] and expanding woven stainless-steel meshes[7-9] have been reported in animal experiments.

Recently, intravascular stents have been implanted in humans to prevent occlusion and restenosis after PTCA.[11] The endoprosthesis used in this first clinical series consisted of a new self-expandable stainless-steel mesh.[11] The early assessment immediately after stent implantation showed an additional morphologic improvement over the PTCA results, affecting both the stenotic and nonstenotic segments, which demonstrates the intrinsic dilating force of the stent. Sigwart et al[11] have indicated that this prosthesis has an elastic radial force that tends to dilate the artery when the

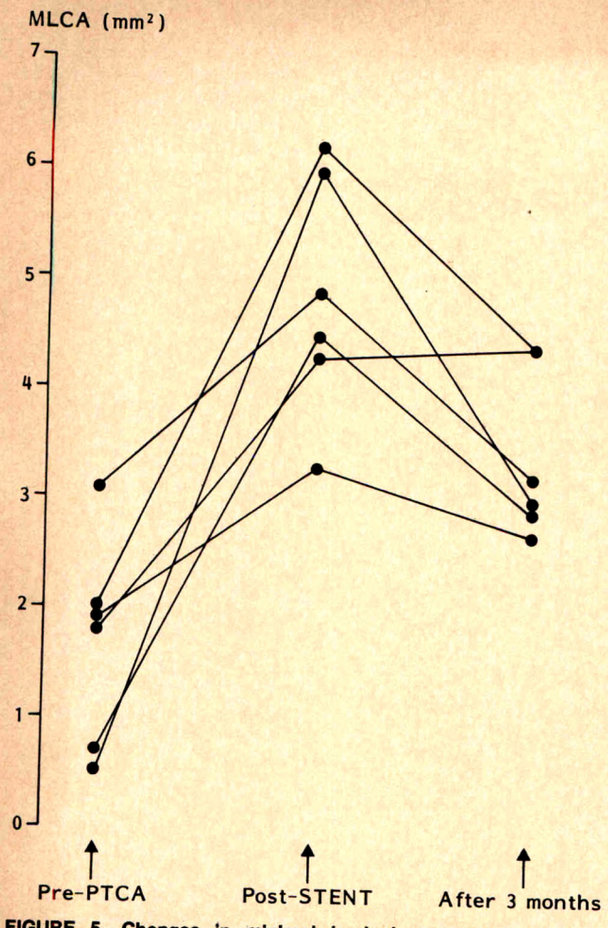

FIGURE 5. Changes in minimal luminal cross-sectional area (MLCA) between pre-angioplasty (pre-PTCA) and immediately after stent implantation (post-STENT) and after a 3-month follow-up.

vessel caliber is less than that of uncontrained stent diameter. Dilatation continues until an equilibrium is achieved between the circumferential elastic resistance of the arterial wall and the dilating force of the prosthesis. Previously, Wright et al[10] showed that the expansile pressure depends on the recipient vessel diameter and on the intrinsic dilating force of the stent itself. The present study confirms—in human beings—the dilating capacity of the stent.

In this study, changes in the nonstenotic segments are reflected in the significant increase observed in the interpolated reference diameter after stent implantation. In the interpretation of this result, 3 facts have to be considered with regard to the determination of the reference diameter.

First, the "interpolated" technique for the determination of the reference diameter incorporates in its computation all the individual diameter values of the proximal and distal coronary segments, which invariably include stented, but nonstenotic segments. Second, the stent size is selected so as to have in its unconstrained state a diameter 0.5 mm larger than the vessel in which it is to be implanted, to ensure that the device will be securely anchored. Third, as the stent has a length ranging from 15 to 22 mm, it is not surprising that the radial force exerted by the stent has a dilating effect on the nonstenotic segments included in the computation of the interpolated reference diameter.

All the long-term experimental studies have shown that in animals neointimal proliferation produces a covering of the stent's luminal surface. The time taken for the endothelialization process to cover the stent surface depends on the thickness of the wire filaments[7,8,10,11] (3 weeks for the prosthesis used in this study).[11] Neointimal thickening varies from 0.2 to 0.5 mm[9,11] and depends on the diameter of the prosthesis.[8] However, most investigators have not found important angiographic reductions in vessel diameter after stent implantation,[4,8,10,11] except for Dotter in his initial study.[5] In a previous study with conventional analysis of in vivo arteriograms, neointimal thickening was not described.[9] In contradistinction, our study demonstrates that a small diffuse narrowing of the vessel's lumen is detectable by quantitative coronary angiography. In the present study, neointimal proliferation was estimated to produce a 0.200-mm reduction in vessel diameter, corresponding to a 11 ± 3% reduction in the stenotic percentage diameter. These results are consistent with animal studies on neointimal thickening[9,11] occurring after stent implantation.

Intraaortic Balloon Pumping for Prolonged Circulatory Support

PAUL S. FREED, MS, TARIK WASFIE, MD, BARINA ZADO, MD, and ADRIAN KANTROWITZ, MD

Prolonged circulatory support with an intraaortic balloon pump (IABP) is controversial, in part because it has not been performed frequently enough to base treatment policy on adequate data. To help clarify this problem, 733 cases of consecutive patients who were supported by IABP between 1967 and 1982 were analyzed. Twenty-seven patients were supported for 20 days or more (range 20 to 71). Twelve (44%) had prior histories of chronic congestive heart failure. Complications were more frequent in prolonged-support patients than in those assisted for <20 days (vascular, 37% vs 15%, p = 0.001; infectious, 67% vs 25%, p = 0.0001; and bleeding, 26% vs 15%, p = 0.04, respectively). The survival rate of prolonged-support patients, however, was 63% (17 of 27), essentially the same as that of the controls (57%, p = 0.5). Of 17 prolonged-pumping patients discharged alive from the hospital, 9 died within 6 months but 8 survived >2 years. Among congestive heart failure patients, none was a long-term survivor. Prolonged IABP support in congestive heart failure patients lacking surgically correctable lesions can extend life while arrangements for definitive therapy are made (transplant, permanent mechanical assistance). Where definitive therapy is unavailable, IABP may provide additional months of life.

(Am J Cardiol 1988;61:554–557)

Although clinical efficacy of intraaortic balloon pumping (IABP) for short-term support is well documented,[1–5] little has been reported on prolonged IABP.[6–10] The present report attempts to determine the morbidity, mortality and therapeutic efficacy of prolonged IABP with data obtained in a retrospective study of a 16-year experience.

Methods

Between 1967 and 1982, 872 attempts to perform IABP were made in 733 patients, 37 of them at Maimonides Medical Center in New York and the remainder at Sinai Hospital of Detroit.[5] Details of technique, adjunctive medical management and type of equipment used have been described previously.[11–14]

Throughout our experience, we attempted to remove the intraaortic balloon pump when the patient was "hemodynamically stable" or a complication occurred which made the risk/benefit ratio excessively high, e.g., threatened loss of a limb in a patient pumped for preoperative support. Generally, if the cardiac index was >2.2 liter/min/m^2, pulmonary capillary pressure <18 mm Hg and arterial blood pressure normal, assistance was discontinued. Alternatively, the balloon drive pressure was reduced to below the patient's systolic pressure for 30 to 60 minutes, the patient observed, and the balloon removed if no trend toward hemodynamic deterioration resulted. In patients in whom circulatory decompensation developed during trial discontinuation of IABP, weaning was attempted. The drive pressure was decreased by 5 to 10 mm Hg/hour, intravascular fluid volume adjusted and digitalis, diuretics, nitrates and (since 1979) oral vasodilators administered. When the drive pressure reached a level below the patient's diastolic pressure, IABP was discontinued and the balloon removed. If the patient's hemodynamic status deteriorated during

CHF = congestive heart failure.

weaning, full-scale IABP was resumed and weaning attempted again 6 to 24 hours later.

In 27 patients IABP was continued for 20 days or longer before weaning could be accomplished. Findings in these patients, the "prolonged-support group," were compared with those of a control group of 672 patients in whom IABP was performed for shorter periods (1 hour to 19 days). For purposes of analysis, all complications that could not be assigned with certainty to another cause were treated as due to IABP.

The statistical significance of differences between categorical variables was determined by means of chi-square analysis; continuous variables were compared by means of the 2-tailed Student's *t* test. A p value of 0.05 or less was regarded as significant.

Observations

Duration of intraaortic balloon pumping, age, sex and preexisting conditions: For the 27 patients in the prolonged-support group, the duration of assistance ranged from 20 to 71 days (average 33 days, median 34 days). The mean age of the patients was 57 years (range 33 to 77). Twenty-three were men and 4 women. In the control group, the average duration of IABP was 96 hours (median 76 hours). The mean age of the patients was 57 years (range 17 to 87); 503 were men and 169 were women.

Table I compares the distribution of preexisting conditions (originated before the present hospital admission) in the prolonged-support and control groups. The 2 groups differed significantly only in the frequency of chronic congestive heart failure (defined as impairment in cardiac function with inadequate cardiac output necessary to meet the metabolic needs of the body as manifested by signs and symptoms of systemic or pulmonary venous congestion, or both).

Indications for intraaortic balloon pumping: Table II contrasts the frequencies of indications for IABP in the 2 groups. The frequency of congestive heart failure as an indication for balloon support was 37% in the prolonged-support group and 9% in the control group; this difference was highly significant. Cardiomyopathy and ventricular septal defect also were significantly more frequent in the prolonged IABP group. Whereas there were many patients pumped prophylactically (preoperative or catheterization support) in the control group, no patients were on prophylactic IABP in the prolonged-support group. All but the 5 prolonged-support patients with unstable angina were experiencing heart failure just prior to assistance.

Cineangiocardiography: Cardiac catheterization and angiocardiography were performed in 23 of the 27 patients of the prolonged-support group (Tables III and IV). In 10, the left ventricular ejection fraction was 35% or less and in 9 the left ventricular end-diastolic pressure was 25 mm Hg or more. In 21 patients, coronary occlusion of various degree was demonstrated. Three patients had acquired ventricular septal defects; 7, mitral regurgitation; and 10, left ventricular aneurysms.

Complications: Table V compares the incidence of complications in patients who received prolonged support and those who did not. The frequencies of vascular, infectious and bleeding complications were higher in patients subjected to prolonged IABP.

Many of the complications in both groups were transient and minor. Significant complications in the prolonged-support group included 2 instances of ischemic neuropathy that required physiotherapy for residual impairment. Thromboembolism necessitated transmetatarsal amputation in 1 patient. Another had gangrene of the foot at death. Two patients died of heart failure exacerbated by septicemia.

Surgery: After or during IABP support, 12 prolonged-support patients had open-heart surgery (Tables III and IV), of whom 10 survived to leave the hospital. Two patients died, 1 of septicemia and 1 of congestive heart failure.

Survival: Of the 27 patients, 17 (63%) were discharged alive. Five patients died during IABP and 5 shortly after its termination. Eight of the 17 patients discharged alive survived longer than 2 years (patients 14–16, 18, 21, 22, 24 and 25 in Table IV). The remaining 9 died within 6 months, in all instances but 1 (patient

20, cerebrovascular accident) of congestive heart failure.

Discussion

Theoretic considerations would support the expectation that patients receiving prolonged IABP support are to experience more complications and shorter survival than those assisted for shorter periods of time.[15,16] This prevailing opinion discourages attempts to maintain patients on IABP support for more than a few days. However, our findings only partially confirmed this expectation. Although complication rates in the prolonged-support group were substantially higher, the survival rate was the same as that of the controls. Many of the increased complications were minor, although 2 were contributory to the patient's death.

All types of complications (vascular, infectious and bleeding) of IABP were significantly more frequent in the prolonged-support group. Although the rate of local infection did not appear to be related to the duration of IABP, the incidence of fever and bacteremia did.[5] The rate of bacteremia seemed to rise after 10 days of assistance. Although the majority of patients recovered completely (7 of 9 instances), the risk of death from septicemia superimposed on an already failing heart is obviously real.

All patients in this study, but especially those in the prolonged-support group, had multiple invasive pro-

cedures and were carefully observed for an extended time interval. Because of this, and the policy of attributing complications of doubtful origin to IABP, the frequency of infectious complications attributed to the support procedure was undoubtedly overestimated.

The percentage of prolonged-support patients surviving to hospital discharge was essentially the same as that of the controls, 63 versus 57% (p = 0.5). This finding may in part be due to the fact that the sickest patients died before 20 days of support elapsed, and thus were excluded from the prolonged-support group.

A more interesting finding was that 9 of the 17 patients discharged from the hospital died within 6 months, whereas the remaining 8 survived more than 2 years. As Table IV shows, none of the long-term survivors had a prior history of chronic congestive heart failure, but 7 of the 9 who died early did.

Thus, our study identified 2 types of patient. The first type included those who benefited temporarily from support and could be discharged from the hospital, only to succumb within 6 months, and the second included those with prolonged IABP support and concomitant corrective surgery who became long-term survivors. The 2 groups could be distinguished by a history of chronic congestive heart failure.

It must be noted that most of the prolonged-support patients were treated between 1970 and 1977. Clinical practice at that time was to delay cardiac surgery for treatment of mechanical lesions until the margin of a myocardial infarct was fibrosed (3 to 4 weeks) and the hemodynamic status of the patient stabilized. This accounts for the large percentage of surgical cases among the prolonged-support group (12 of 27). Current practice in general and at our institution is more aggressive and would have resulted in much earlier operation in most of the 12 patients.

Because this was a retrospective study and the number of prolonged-support patients was small, its findings have the standing of relevant hypotheses for investigation in a prospective study rather than of established conclusions. Nevertheless, conclusions of interest from a clinical management perspective can be proposed, including the fact that maintaining balloon-dependent patients in whom surgical correction of anatomic lesions is not possible on prolonged IABP support is feasible, although at the cost of an increased complication rate. Such practice may be justifiable when the patient has to wait for definitive treatment, such as heart transplantation, or the implantation of a mechanical heart-assist device.[17-19] In patients in whom definitive therapy cannot be performed, prolonged IABP may result in sufficient improvement in cardiac function to prolong life a few months.

TABLE V Complication Rates in Patients Supported by Intraaortic Balloon Pumping

Complication	Prolonged-Support Pts (n = 27) No. (%)	Controls (n = 672) No. (%)	p Value
Vascular*	10 (37)	100 (15)	0.001
Infectious †	18 (67)	164 (25)	0.0001
Bleeding	7 (26)	94 (15)	0.04

* Vascular complications include pain in the leg, neurologic complications, thromboemboli, aortic dissection and amputation.

† Infectious complications include fever, local wound infection and bacteremia.

Risks Associated With Intraaortic Balloon Pumping in Patients With and Without Diabetes Mellitus

TARIK WASFIE, MD, PAUL S. FREED, MS, MELVYN RUBENFIRE, MD, WALDEMAR WAJSZCZUK, MD, PAULA REIMANN, RN, WITOLD BROZYNA, MD, M. ANTHONY SCHORK, PhD, JAY KOZLOWSKI, MD, and ADRIAN KANTROWITZ, MD

Between 1967 and 1982, intraaortic balloon pumping (IABP) was attempted in 733 patients. Of these, 132 were diabetic: 51 patients were managed with diet alone, 46 patients took oral hypoglycemic agents and 35 patients required insulin. Vascular complications associated with IABP occurred in 34% of the insulin-dependent diabetics, in 18% of other diabetics and in 14% of nondiabetic patients. Infectious complications were 37, 22 and 25%, respectively. Seventy-five diabetic patients (57%) were discharged alive from the hospital after balloon pumping, essentially the same proportion as among nondiabetic patients (58%). It is concluded that although diabetics incur a higher complication rate, IABP is not contraindicated.

(Am J Cardiol 1988;61:558–562)

Diabetes mellitus (DM) is associated with an increased frequency of vascular occlusive disease and infections.[1–5] It is not known, however, if these sequelae place diabetic patients at heightened risk of complications due to intraaortic balloon pumping (IABP). We compared the outcome of IABP in diabetic and nondiabetic subjects in a series of 733 patients for whom this mechanical cardiac assistance was attempted.

Methods

Over almost 16 years between June 1967 and December 1982, we attempted to perform IABP in 733 patients (37 at Maimonides Medical Center in Brooklyn, New York, and 696 at Sinai Hospital of Detroit, Michigan). The details of technique—performance of balloon pumping, adjunctive medical management and equipment used—have been described previously.[6–9]

The 733 patients were subjected to 872 attempts to insert the IABP. For each insertion attempt, the patient's chart was examined by a physician to determine identifying information, the patient's age and sex, relevant prior history, the indication for balloon pumping, the dates of balloon insertion and removal, the complications of the procedure, the hospital location where the procedure was attempted, type of balloon used, causes of insertion failure, therapy given before, during and after mechanical assistance, findings at angiocardiography and the nature of any associated cardiac surgical procedure. Also recorded were the duration of balloon pumping and the patient's status at hospital discharge. Where available, autopsy findings were noted.[10]

In all, 190 variables for each insertion attempt were coded and entered into a computer for analysis. For the present study, subsets of data on diabetic and nondiabetic patients were extracted for analysis.

Percutaneous balloon insertion technique was attempted in 95 insertions (17 in diabetic patients).

Data analysis: Complications of balloon pumping were classified as follows.

Category I: Spontaneous resolution without treatment, with balloon pump in situ (e.g., loss of peripheral distal pulse, serosanguinous discharge, temperature spike). *Category II:* Resolution after treatment or removal of balloon pump (e.g., ischemia of limb, fever, bleeding from arteriotomy, infection). *Category III:* Residual deficit (e.g., foot drop, neuropathy). *Category IV:* Contributory cause of death (e.g., retroperitoneal bleeding from ruptured iliac artery, bacteremia, cardiac arrest during femoral artery embolectomy under general anesthesia).

From Sinai Hospital of Detroit, Detroit, Wayne State University, School of Medicine, Detroit, and The University of Michigan, Ann Arbor, Michigan. This study was supported by grants from The General Research Fund of Sinai Hospital of Detroit, Detroit, Michigan, and the Cardiac Surgery Research Foundation, New York, New York. Manuscript received July 1, 1987; revised manuscript received and accepted October 26, 1987.

Address for reprints: Adrian Kantrowitz, MD, Sinai Hospital of Detroit, 6767 West Outer Drive, Detroit, Michigan 48235.

For several conditions detected during or after IABP (e.g., fever, bleeding, organ emboli), it was impossible to establish a cause-effect relation between attempted or accomplished pumping and the occurrence of the complication. Therefore, unless the complication could be shown to be unrelated to IABP, it was attributed to the procedure.

Differences between categorical variables were tested for statistical significance using chi-square analysis; values for continuous variables were compared using the 2-tailed Student's *t* test. A p value ≤ 0.05 was considered significant. A multivariate risk factor analysis with a logistic regression model[11] was used to determine if any combinations of predictor variables could define subsets of patients at heightened risk of complications.

Results

Of the 733 patients, 132 had DM by history with the diagnosis confirmed during the hospitalization in which IABP was attempted. In 652 patients (89%), the first attempt to insert the IABP succeeded; 46 patients (6%) required 2 or more attempts. The IABP could not be put into place in 35 patients (5%). Thus, attempts to insert the IABP were successful in 95% of patients overall. After multiple attempts, the rate of failure to insert the IABP was no different in the diabetic and nondiabetic patients (4 vs 5%, p = 0.6).

Seventy-nine patients were men (60%), and 53 were women (40%). They ranged in age from 35 to 78 years. The median age for the group was 60 years (58 years for men and 61 years for women). Forty-one patients (31%) were managed with diet alone, 46 patients (35%) took oral hypoglycemic agents and 35 (27%) required insulin. In the remaining 10 patients, no information about the management of the diabetes was available.

In the nondiabetic group there were 468 men (77%) and 133 women (23%). Women constituted half of the insulin-dependent diabetic patients and 34% of the noninsulin-dependent diabetic patients. They ranged in age from 16 to 87 years. The median age of the nondiabetic subset was 58 years (57 for men and 62 for women).

For the purposes of analysis, the patients were regrouped into 3 sets: nondiabetic (601), diabetic, noninsulin dependent (97, including the 10 for whom management information was unavailable) and diabetic, insulin-dependent (35). For some analyses, the 2 latter sets had to be merged because of the small number of patients in certain subsets (e.g., insulin-dependent diabetics with a history of valvular heart disease).

Table I compares the distribution of relevant prior diagnoses in diabetic and nondiabetic patients. Diabetic patients had a higher rate of systemic hypertension, 48% (54% for insulin-dependent diabetics, 46% for other diabetics) than nondiabetics (32%). However, the frequencies of coronary artery disease, myocardial infarction, congestive heart failure, peripheral vascular disease, valvular heart disease and cerebrovascular accidents were essentially the same in the 2 groups.

TABLE I Distribution of Prior Diagnoses Among Diabetic and Nondiabetic Patients

	Diabetic Pts (n = 132)		Nondiabetic Pts (n = 601)		
Condition	No.	Frequency (%)	No.	Frequency (%)	p Value
AMI	60	(45)	264	(44)	0.7
CAD	91	(69)	375	(62)	0.1
CHF	34	(26)	119	(20)	0.1

Shock	35	(27)	163	(27)	0.8
Unstable angina	36	(27)	133	(22)	0.2
VSD	2	(2)	18	(3)	0.3
Weaning from oxygenator	9	(7)	58	(10)	0.3

* Some patients presented with more than 1 indication.
CO = cardiac output; MR = mitral regurgitation; PO = postoperative; VSD = ventricular septal defect; other abbreviations as in Table I.

Table II shows the frequencies of the various indications for IABP in diabetic and nondiabetic patients. Unstable angina, cardiogenic shock and preoperative support were by far the most frequent indications in both groups. The frequency of congestive heart failure as an indication was greater in diabetic (14%) than in nondiabetic patients (9%). Mitral regurgitation, arrhythmias and ventricular septal defects occurred less frequently in diabetics, but the statistical significance of this difference could not be demonstrated because of the small number of patients.

Table III compares the 3 sets of patients for the frequency and severity of complications of IABP. Vascular injury includes loss of peripheral pulse, pain in the leg, neurologic complications, thromboembolism and amputation. The observed frequency was highest in insulin-dependent diabetic and least in nondiabetic

Abbreviations as in Table I.

patients. Vascular complications are more frequent among women than men (19 vs 12%) in the nondiabetic population, but this difference disappeared in the presence of insulin-dependent diabetes (Table IV). However, among all diabetic patients, the complication rate for women is higher than for men (28 vs 18%, difference not significant). The outcome for those patients with vascular complications was generally favorable. Those with less than complete recovery included 3 patients with pain in the leg who subsequently had femoral angioplasty, 1 patient with neurologic damage who had residual footdrop, 1 patient with thrombosis or emboli who died during femoral embolectomy and 1 patient who required above-the-knee amputation.

The second most frequent type of complication was infectious, which includes fever, local infection and bacteremia. The higher rate of infectious complications in insulin-dependent diabetic patients (37%) was largely due to the relatively high rate of local infections in this group. Bacteremia among diabetic patients was associated with the worst outcome, and 2 of 3 died.

The rate of infectious complications among all patients varied according to where circulatory assistance was initiated: 12% for those patients in whom IABP was initiated in the operating room; 17% in the catheterization laboratory; and 25% in the cardiac or surgical intensive care unit.

Seventy-five diabetic patients (57%) were discharged alive from the hospital after IABP, which was essentially the same proportion as among nondiabetic patients (Table V and VI). Although survival varied according to sex and type of diabetes (Table VI), none of the differences reached statistical significance.

The influence of prior medical history on survival of diabetic and nondiabetic patients is listed in Table VI. The survival of patients in both groups was nearly the same for all antecedent conditions except peripheral vascular disease. Table VII shows survival according to the indication for assisted circulation. Again, diabetic patients fared essentially as well as nondiabetics, except for those with unstable angina. Only 72% of the diabetic patients in the latter group were alive at hospital discharge compared with 88% of the nondiabetic patients.

Definition of patient subset by logistic regression analysis: Logistic regression models that attempted to find combinations of predictor variables (demographics, preexisting condition, indication and duration of

IABP support) to explain complications (categorized into severity of symptom subgroups) were of limited value. When a second or third predictor was entered into a model, only a very minor additional variation in the complication was accounted for in comparison with the amount of variation accounted for by a single predictor variable. Further, when combinations of symptoms (for a given complication) and predictor variables were considered, the sample sizes were usually too small to make the logistic model stable.

Discussion

The frequency of overt DM in the U.S. is about 3 to 4%.[12] Among our group of IABP patients the frequency was 18% (Table VIII), which is consistent with the high frequency of coronary artery disease[13] and myocardial infarction in diabetics.[5] In those with severe diabetes, the incidence of cardiac disorders may be 2 or 3 times that of the general population. Women with diabetes are said to be at especially high risk.[2,14] This is consistent with our findings: 40% of diabetic patients requiring balloon pumping were women, whereas among nondiabetics only 23% were women.

As in other series,[15,16] vascular injuries were common complications of IABP. We found their frequency to be considerably higher among diabetic (22%) than among nondiabetic patients (14%). Insulin-dependent patients accounted for most of this increase; the frequency of vascular damage was 34% in this group. Although there was a significant difference in the incidence of vascular complications between male and female patients among the nondiabetics, an observation related to the size of the femoral artery in the female,[17] it did not reach statistical significance in the diabetic patients. On the other hand, male diabetic patients showed significant changes in the rate of vascular complications compared with nondiabetic men; these changes were not achieved in the female population. This finding may be related to the degree of peripheral vascular disease in diabetic men.[18] Most patients with vascular complications eventually recovered completely. As in other series,[19,20] the amputation rate was <1%.

The rate of local wound infection was also significantly higher in diabetic (9%) compared with nondiabetic patients (4%). Various investigators have demonstrated defective function of polymorphonuclear leukocytes in both adult and juvenile diabetics,[21–23] a finding that may account for the predisposition of such patients to infection.

The question of whether the use of a percutaneous balloon would alter any of these findings is timely. In this retrospective study it was not possible to determine this because the selection of the type of balloon used was based in part on the condition of the patients. To eliminate this bias, a separate prospective randomized study was carried out[24]; this study concluded that although "percutaneous technique for IABP insertion is faster than the surgical technique, and technically easy, it is associated with a higher incidence of vascular complications."

TABLE VII Survival in Diabetic and Nondiabetic Patients According to Indication for Balloon Pumping

	Diabetic Pts		Nondiabetic Pts

TABLE VIII Prevalence of Diabetes Mellitus

	In Balloon Pump Series		In General Population*
	No.	(%)	(%)
Insulin-dependent	35	(4.8)	(0.6–1.3)
Noninsulin-dependent	97	(13.2)	(2.7)
Total	132	(18.0)	(3.3–4.0)

* From reference 12.

Heart disease is the most frequent cause of death among diabetic subjects.[25] The mortality rate of diabetic subjects is almost 3 times that of the general population, and for each specified cardiovascular cause, mortality is distinctly higher among diabetics.[18] In our diabetic patients, the 57% overall survival rate did not differ from that of nondiabetics (58%, $p = 0.6$). As in the nondiabetic, the diabetic woman had a lower survival rate (55%) than the diabetic man (58%), although the difference was not significant. Insulin dependence does not appear to influence the probability of survival. The fact that most diabetic patients in this series were in adequate control of their condition may account for this finding.[14]

These data support the conclusion that DM increases the risk of minor vascular and infectious complications associated with IABP, especially for insulin-dependent patients. This agrees with the expectation that diabetes is an important complicating factor. However, since we did not obtain evidence that the risk of permanent sequelae is significantly higher among diabetic patients, and survival for diabetic and nondiabetic patients is the same, the implication is that IABP is not contraindicated in diabetic subjects. In addition, the higher incidence of infectious complications suggests that operating room standards for sterility be used whenever balloon pump insertion is attempted in diabetic patients.

Now Available in 20mg Capsules
FOR GREATER DOSING CONVENIENCE
PROCARDIA®
(NIFEDIPINE)
Capsules 10 mg and 20 mg
PROCARDIA® (nifedipine) means your mixed angina patients will have significant reduction in angina attacks and nitroglycerin consumption.[1] And they can be more active—both working and at leisure.
feeling better...doing more
Please see PROCARDIA® (nifedipine) brief summary on next page.

feeling better...doing more

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg and 20 mg*

–Effective dosage range is 30-120 mg/day

For most patients, start with 10 mg *t.i.d.*, and titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because PROCARDIA decreases peripheral vascular resistance (occasional patients have had excessive hypotension), careful monitoring of blood pressure during initial administration and upward dosage titration is suggested, especially for patients taking other drugs known to lower blood pressure. Occasional patients have developed increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases.

–Offers a favorable safety profile

Most frequently reported side effects associated with PROCARDIA therapy, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients; transient hypotension in about 5%; palpitation in about 2%; syncope in about 0.5%.

Brief Summary
PROCARDIA® (nifedipine) Capsules For Oral Use

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta-blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See WARNINGS.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out. In PROCARDIA treated patients where surgery using high dose fentanyl anesthesia is contemplated, the physician should be aware of these potential problems and, if the patient's condition permits, sufficient time (at least 36 hours) should be allowed for PROCARDIA to be washed out of the body prior to surgery.

Increased Angina and/or Myocardial Infarction: Rarely, patients, particularly those who have severe obstructive coronary artery disease, have developed well documented increased frequency, duration and/or severity of angina or acute myocardial infarction on starting PROCARDIA or at the time of dosage increase. The mechanism of this effect is not established.

Beta Blocker Withdrawal: Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients, usually receiving a beta blocker, have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See WARNINGS.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

Laboratory tests: Rare, usually transient, but occasionally significant elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT and SGPT have been noted. The relationship to PROCARDIA therapy is uncertain in most cases, but probable in some. These laboratory abnormalities have rarely been associated with clinical symptoms, however, cholestasis with or without jaundice has been reported. Rare instances of allergic hepatitis have been reported.

Limited clinical studies have demonstrated a moderate but statistically significant decrease in platelet aggregation and increase in bleeding time in some PROCARDIA (nifedipine) patients. No clinical significance for these findings has been demonstrated. Positive direct Coombs test with/without hemolytic anemia has been reported.

Although PROCARDIA has been used safely in patients with renal dysfunction and has been reported to exert a beneficial effect in certain cases, rare, reversible elevations in BUN and serum creatinine have been reported in patients with pre-existing chronic renal insufficiency. The relationship to PROCARDIA therapy is uncertain in most cases but probable in some.

Drug interactions: Beta-adrenergic blocking agents: (See INDICATIONS AND WARNINGS.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal volunteers. The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with coronary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which digoxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports of patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing PROCARDIA to avoid possible over- or under-digitalization.

Coumarin anticoagulants: There have been rare reports of increased prothrombin time in patients taking coumarin anticoagulants to whom PROCARDIA was administered.

Cimetidine: A study in six healthy volunteers has shown a significant increase in peak nifedipine plasma levels (80%) and area-under-the-curve (74%) after a one week course of cimetidine at 1000 mg per day and nifedipine at 40 mg per day. Ranitidine produced smaller, non-significant increases. If nifedipine therapy is initiated in a patient currently receiving cimetidine, cautious titration is advised.

Carcinogenesis, mutagenesis, impairment of fertility: Nifedipine was administered orally to rats for two years and was not shown to be carcinogenic. When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose. *In vivo* mutagenicity studies were negative.

Pregnancy: Pregnancy Category C. Nifedipine has been shown to be teratogenic in rats and embryotoxic in rats, mice and rabbits. There are no adequate and well controlled studies in pregnant women. PROCARDIA should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: The most common adverse events include dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Additionally, the following have been reported: muscle cramps, nervousness, dyspnea, nasal and chest congestion, shortness of breath, diarrhea, constipation, gastrointestinal cramps, flatulence, inflammation, joint stiffness, shakiness, jitteriness, sleep disturbances, blurred vision, difficulties in balance, dermatitis, pruritus, urticaria, fever, sweating, chills, sexual difficulties, thrombocytopenia, anemia, leukopenia, purpura, allergic hepatitis, gingival hyperplasia, depression, paranoid syndrome, transient blindness at the peak of plasma level, erythromelalgia, and arthritis with ANA (+). Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

HOW SUPPLIED: PROCARDIA soft gelatin capsules are supplied in:
Bottles of 100: 10 mg (NDC 0069-2600-66) orange #260; 20 mg (NDC 0069-2610-66) orange and light brown #261. Bottles of 300: 10 mg (NDC 0069-2600-72) orange #260; 20 mg (NDC 0069-2610-72) orange and light brown #261. Unit dose packages of 100: 10 mg (NDC 0069-2600-41) orange #260; 20 mg (NDC 0069-2610-41) orange and light brown #261.

The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

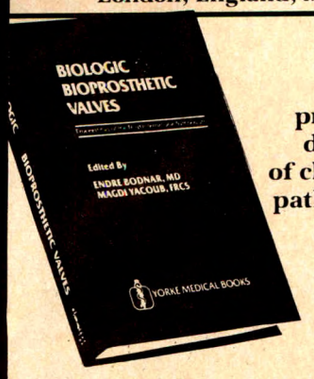
Biologic & Bioprosthetic Valves

Proceedings of the Third International Symposium London, England, May 21-23, 1985



The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.

lited by Endre Bodnar, MD, and Magdi Yacoub, FRCS
BN 0-914316-49-4, 920 pp., May, 1986, $125.00

order your copy of this important new book use the der form below.

The Third International Symposium on Cardiac Bioprostheses as held May 21-23, 1985, at the Grosvenor House Hotel, London. x years have passed since the first meeting of this kind was held Munich and 3 years since the second conference in Rome. The assessment of the state of the art with biologic and bioprosthetic lves seems to have become a regular 3-yearly fixture reflecting e fast development of these devices, as well as the desire of rgeons and academics working in this field to share experiences, change ideas, and to resolve problems together.

The London meeting brought together surgeons, cardiologists, thologists, engineers, and basic scientists, and the 3-day program commodated 96 formal presentations with nearly 7 hours of scussion. It is a credit to the session chairmen and participants at the discussions were frank, outspoken, but fair and always to e point, and they have been added to this volume, and they rtainly enhance its value.

This volume incorporates the work of the best specialists in the eld, and should not be missing from your own professional brary.

The Editors are eminently qualified to do this book, Dr. Bodnar is ith the Cardiothoracic Institute, London, England, and Mr. Yacoub with Harefield Hospital, Middlesex, England.

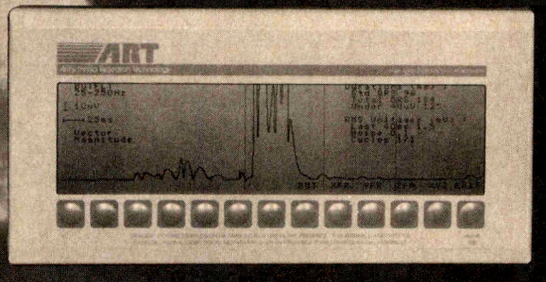
A New Age In Noninvasive Detection Of Ventricular Arrhythmias And Sudden Death Has Dawned.

Science Meets ART.℠



Arrhythmia Research Technology's Model 1200 EPX™ is the world's leader in signal averaging for the detection of "late potentials."

More hospitals use ART than any other device of its kind.

In most cases, signal averaging with "late potentials" is more sensitive and more specific than either Holter monitoring or Radionuclide Ejection Fraction!

Arrhythmia Research Technology...the new noninvasive standard to predict sustained Ventricular Tachycardia and sudden death.

K-DUR™ Microburst Release System™
(potassium chloride) Sustained Release Tablets

INDICATIONS AND USAGE: BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis, in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For the prevention of potassium depletion when the dietary intake is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure, hepatic cirrhosis with ascites, states of aldosterone excess with normal renal function, potassium-losing nephropathy, and with certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: Chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g., spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium.

All solid dosage forms of potassium chloride supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS: Hyperkalemia—In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium Sparing Diuretics—Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene) since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal Lesions—Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage or perforation.

K-DUR tablets contain micro-crystalloids which disperse upon disintegration of the tablet. These micro-crystalloids are formulated to provide a controlled release of potassium chloride. The dispersibility of the micro-crystalloids and the controlled release of ions from them are intended to minimize the possibility of a high local concentration near the gastrointestinal mucosa and the ability of the KCl to cause stenosis or ulceration. Other means of accomplishing this (e.g., incorporation of potassium chloride into a wax matrix) have reduced the frequency of such lesions to less than one per 100,000 patient years (compared to 40–50 per 100,000 patient years with enteric-coated potassium chloride) but have not eliminated them. The frequency of GI lesions with K-DUR tablets is, at present, unknown. K-DUR tablets should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic Acidosis—Hypokalemia in patients with metabolic acidosis should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, potassium acetate, or potassium gluconate.

PRECAUTIONS: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis per se can produce hypokalemia in the absence of a deficit in total body potassium while acute acidosis per se can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

Laboratory Tests: Regular serum potassium determinations are recommended. In addition, during the treatment of potassium depletion, careful attention should be paid to acid-base balance, other serum electrolyte levels, the electrocardiogram, and the clinical status of the patient, particularly in the presence of cardiac disease, renal disease, or acidosis.

Drug Interactions: Potassium-sparing diuretics; see **WARNINGS.**

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term carcinogenicity studies in animals have not been performed.

Pregnancy Category C: Animal reproduction studies have not been conducted with K-DUR. It is also not known whether K-DUR can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. K-DUR should be given to a pregnant woman only if clearly needed.

Nursing Mothers: The normal potassium ion content of human milk is about 13 mEq per liter. Since oral potassium becomes part of the body potassium pool, so long as body potassium is not excessive, the contribution of potassium chloride supplementation should have little or no effect on the level in human milk.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: One of the most severe adverse effects is hyperkalemia (see **CONTRAINDICATIONS, WARNINGS,** and **OVERDOSAGE**). There have also been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration, and perforation (see **CONTRAINDICATIONS** and **WARNINGS**); other factors known to be associated with such conditions were present in many of these patients.

The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by taking the dose with meals or reducing the dose.

Skin rash has been reported rarely.

OVERDOSAGE: The administration of oral potassium salts to persons with normal excretory mechanisms for potassium rarely causes serious hyperkalemia. However, if excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, potentially fatal hyperkalemia can result (see **CONTRAINDICATIONS** and **WARNINGS**). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by an increased serum potassium concentration and characteristic electrocardiographic changes (peaking of T-waves, loss of P-waves, depression of S-T segment, and prolongation of the QT-interval). Late manifestations include muscle-paralysis and cardiovascular collapse from cardiac arrest.

Treatment measures for hyperkalemia include the following:

1. Elimination of foods and medications containing potassium and of potassium-sparing diuretics.
2. Intravenous administration of 300 to 500 ml/hr of 10% dextrose solution containing 10–20 units of insulin per 1,000 ml.
3. Correction of acidosis, if present, with intravenous sodium bicarbonate.
4. Use of exchange resins, hemodialysis, or peritoneal dialysis.

In treating hyperkalemia, it should be recalled that in patients who have been stabilized on digitalis, too rapid a lowering of the serum potassium concentration can produce digitalis toxicity.

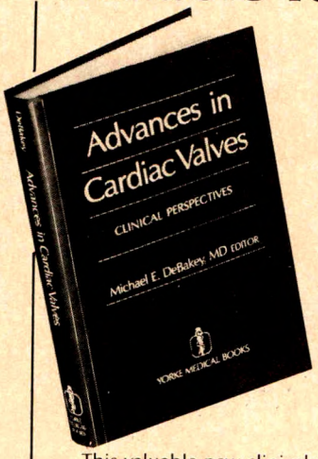
The Most Extensive Compilation of Information on Heart Valve Replacement Available Today!



Advances in Cardiac Valves
Clinical Perspectives

edited by
Michael E. DeBakey, MD

0-914316-40-0, November 1983, 274pp., $35.00

This valuable new clinical reference provides a detailed update on many aspects of mechanical heart valve prostheses, including hemodynamics, clinical results, results in children, non-invasive assessments, special indications, and implant techniques. Each topic is presented in an easily understood style and format which facilitate the comprehension of recent developments in heart valve replacement for the busy clinician.

Each chapter is written by internationally respected physicians and medical scientists each of whom is pre-eminent in his field. All of this information has been co-ordinated by Dr. DeBakey to produce a very readable and informative volume on the state-of-the-art of heart valve replacement with mechanical prostheses. No cardiologist, cardiovascular surgeon, internist, or bioengineer can afford *not* to be knowledgeable about the information in this book.

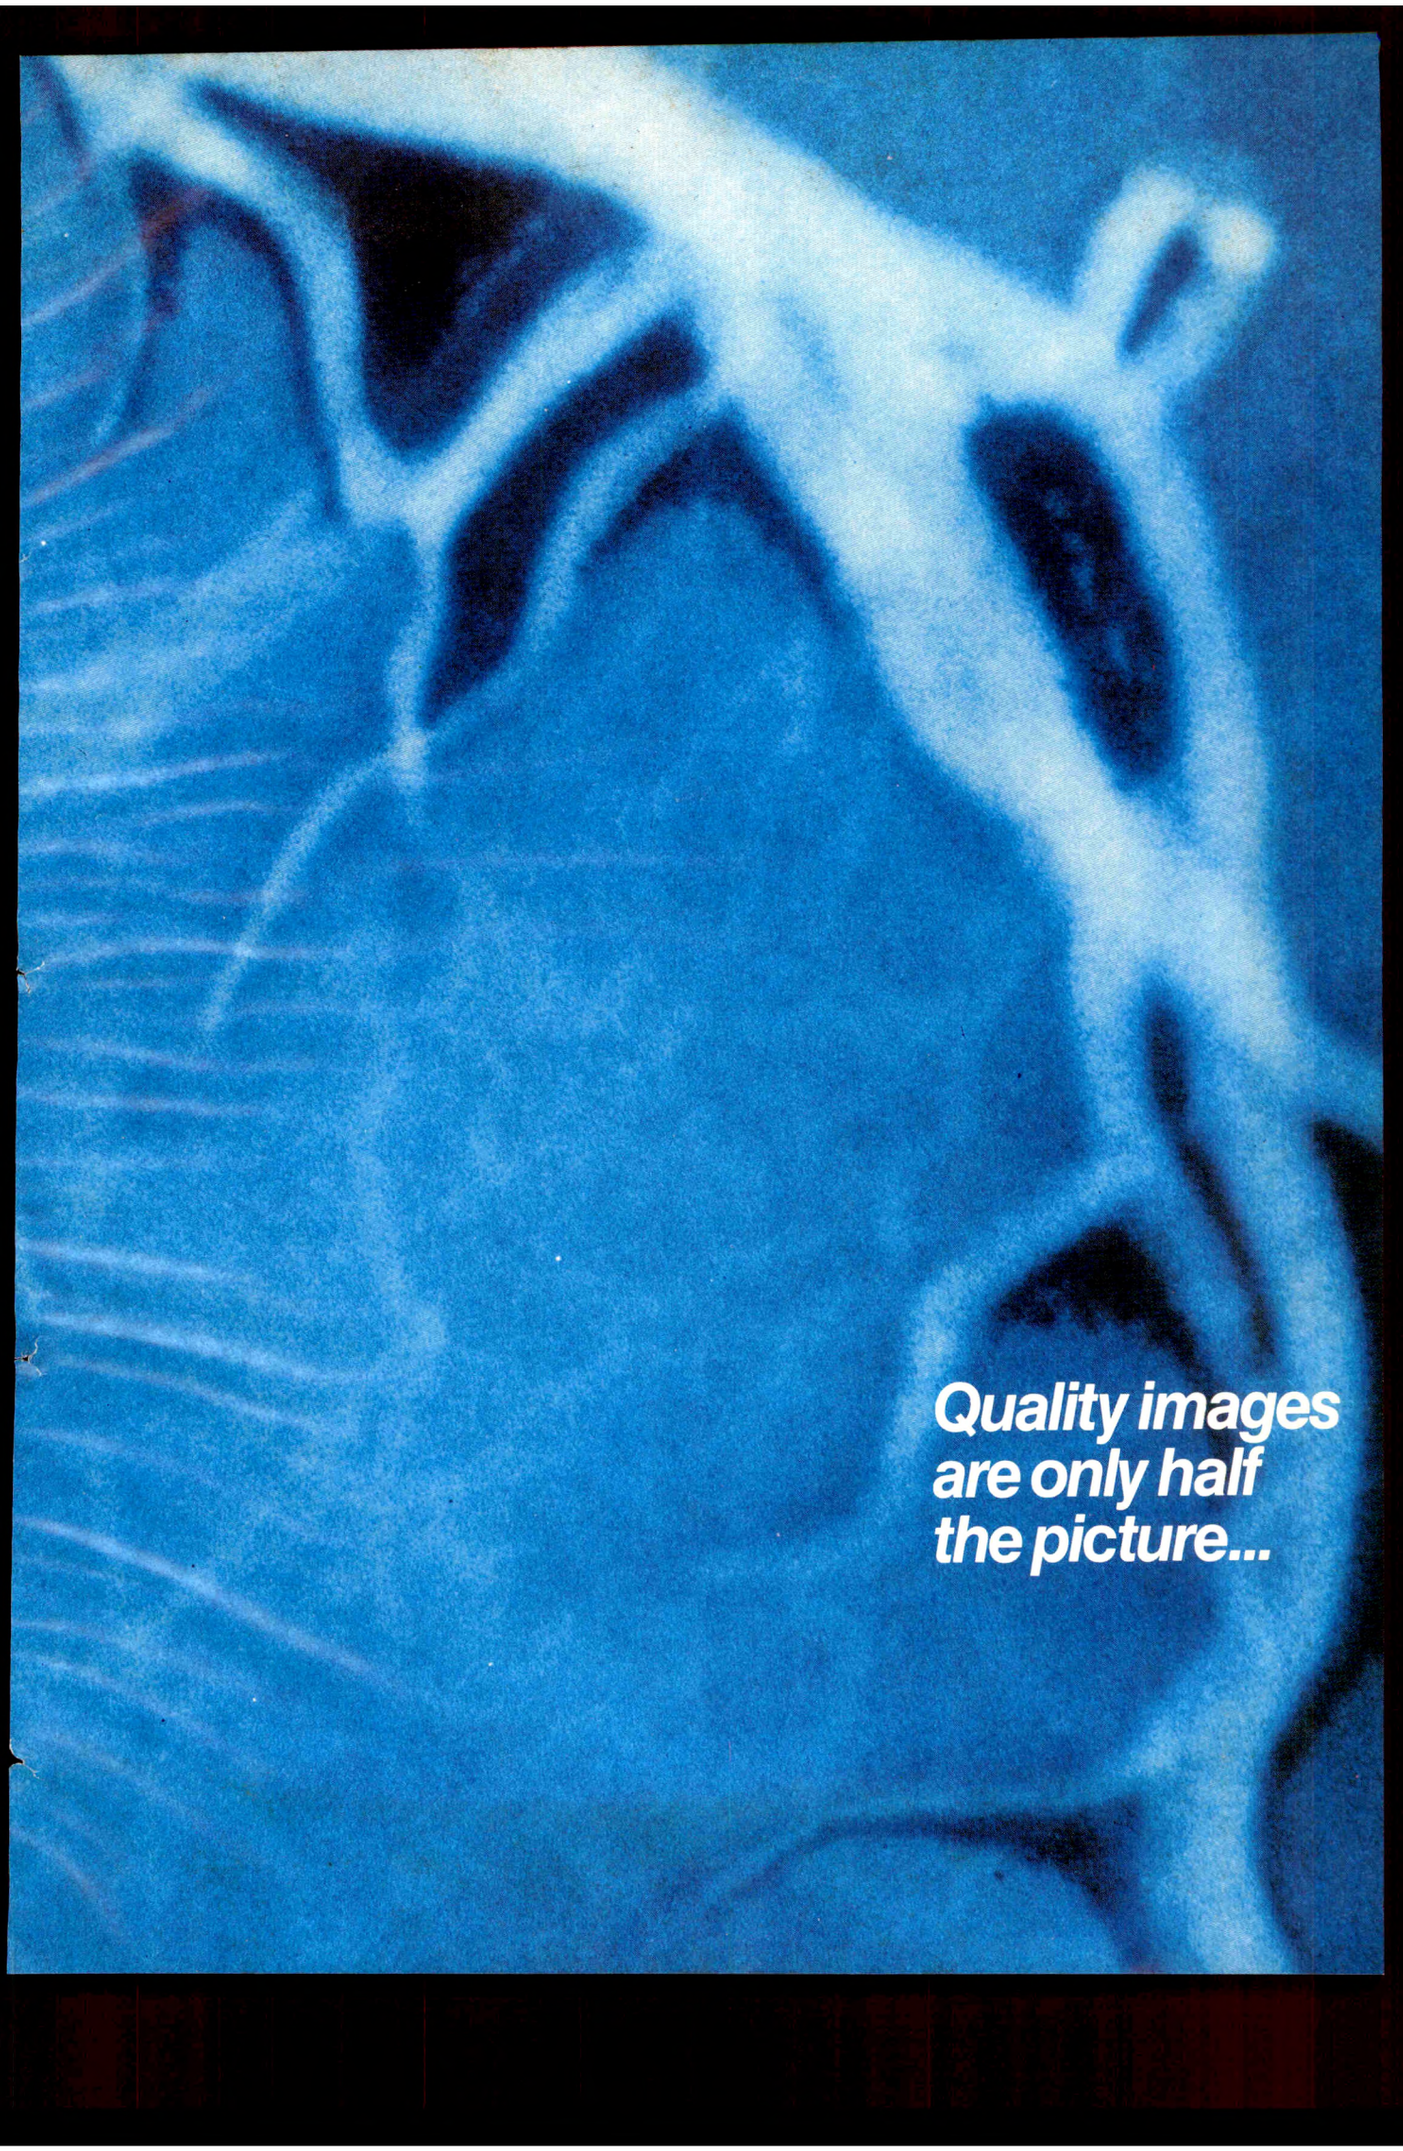
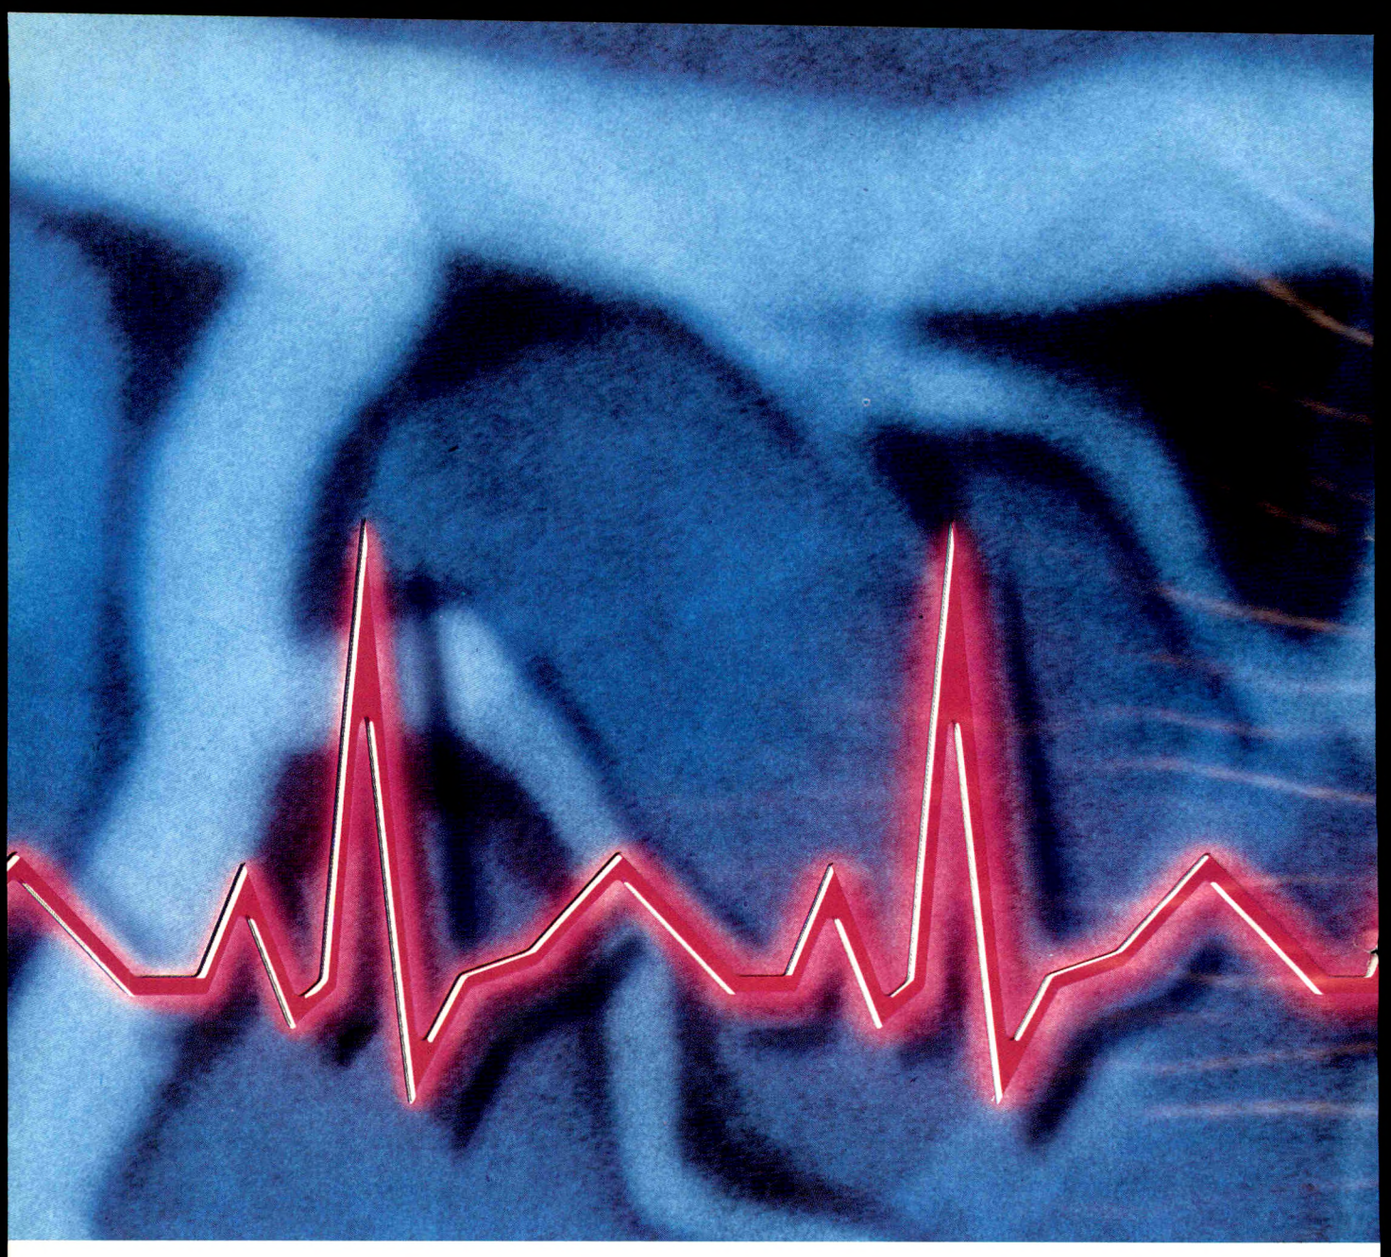
Attenuation of Ventricular Enlargement Following Myocardial Infarction — Effect of Captopril — *Gervasio Anthony Lamas, MD*

Survival and Ventricular Enlargement Following Acute Myocardial Infarction — *Marc A. Pfeffer, MD, PhD*

On-site registration will be held outside the Marquis Ballroom.



Quality images
are only half
the picture...



Lower cardiovascular risk

Coronary and ventricular imaging procedures demand a higher level of performance from contrast media: quality images plus limited interference with cardiac function. Hexabrix is an ideal choice for cardiac imaging for just that reason.

Less effect on cardiac and renal function

Hexabrix offers less interference with cardiac function and less risk of nephrotoxicity when compared with conventional contrast media.[1-4] This is particularly important for procedures such as PTCA, where larger volumes of contrast media are necessary.

Lowest osmolality

Of the three newer contrast agents, Hexabrix offers the lowest osmolality per milligram of iodine (600 mOsm/kg H_2O, versus 796 mOsm for iopamidol-370 and 844 mOsm for iohexol-350). The lower osmolality of Hexabrix reduces undesirable fluid shifts into the vascular space.

F R O M M A L L

s equally important.

Lower risk of clotting *in vitro*

Studies have demonstrated that Hexabrix has a stronger inhibitory effect on red blood cell clotting *in vitro* than iopamidol or iohexol.[5,6]

Lower viscosity

Hexabrix provides a lower viscosity than iohexol-350 or iopamidol-370, for ease of injection, especially in higher-volume procedures.

Please see the following page for references and brief summary of prescribing information.

Quality images and the lowest osmolality

HEXABRIX †

(ioxaglate meglumine 39.3%/ ioxaglate sodium 19.6% injection)

Changing the look of medicine

I N C K R O D T

HEXABRIX† (ioxaglate meglumine 39.3%/ioxaglate sodium 19.6% injection)

HEXABRIX®

Each milliliter of HEXABRIX contains 393 mg of ioxaglate meglumine, 196 mg of ioxaglate sodium and 0.10 mg edetate calcium disodium as a stabilizer. The solution contains 3.48 mg (0.15 mEq) sodium in each milliliter and provides 32% (320 mg/mL) organically bound iodine.

CONTRAINDICATIONS

HEXABRIX is contraindicated for use in myelography. Refer to PRECAUTIONS concerning hypersensitivity. Hysterosalpingography should not be performed during the menstrual period; in pregnant patients; in patients with known infection in any portion of the genital tract; or in patients in whom cervical conization or curettage has been performed within 30 days. Arthrography should not be performed if infection is present in or near the joint.

WARNINGS

Serious or fatal reactions have been associated with the administration of iodine containing radiopaque media. It is of utmost importance to be completely prepared to treat any contrast medium reaction.

As with any contrast medium, serious neurologic sequelae, including permanent paralysis, can occur following cerebral arteriography, selective spinal arteriography and arteriography of vessels supplying the spinal cord. The injection of a contrast medium should never be made following the administration of vasopressors, since they strongly potentiate neurologic effects.

In patients with subarachnoid hemorrhage, a rare association between contrast administration and clinical deterioration, including convulsions and death, has been reported. Therefore, administration of intravascular iodinated contrast media in these patients should be undertaken with caution.

A definite risk exists in the use of intravascular contrast agents in patients who are known to have multiple myeloma. In such instances anuria has developed, resulting in progressive uremia, renal failure and eventually death. Although neither the contrast agent nor dehydration has separately proved to be the cause of anuria in myeloma, it has been speculated that the combination of both may be a causative factor. The risk in myelomatous patients is not a contraindication to the procedure; however, partial dehydration in the preparation of these patients for the examination is not recommended since this may predispose to precipitation of myeloma protein in the renal tubules. No form of therapy, including dialysis, has been successful in reversing the effect. Myeloma, which occurs most commonly in persons over 40, should be considered before instituting intravascular administration of contrast agents.

Administration of radiopaque materials to patients known or suspected to have pheochromocytoma should be performed with extreme caution. If, in the opinion of the physician, the possible benefits of such procedures outweigh the considered risks, the procedures may be performed; however, the amount of radiopaque medium injected should be kept to an absolute minimum. The blood pressure should be assessed throughout the procedure, and measures for treatment of a hypertensive crisis should be available.

Since intravascular administration of contrast media may promote sickling in individuals who are homozygous for sickle cell disease, fluid restriction is not advised.

In patients with advanced renal disease, iodinated contrast media should be used with caution and only when the need for the examination dictates, since excretion of the medium may be impaired. Patients with combined renal and hepatic disease, those with severe hypertension or congestive heart failure and recent renal transplant recipients present an additional risk.

Renal failure has been reported in patients with liver dysfunction who were given an oral cholecystographic agent followed by an intravascular iodinated radiopaque agent and also in patients with occult renal disease, notably diabetics and hypertensives. In these classes of patients there should be no fluid restriction and every attempt made to maintain normal hydration prior to contrast medium injection, since dehydration is the single most important factor influencing further renal impairment.

Caution should be exercised in performing contrast medium studies in patients with endotoxemia and/or those with elevated body temperatures.

Reports of thyroid storm occurring following the intravascular use of iodinated radiopaque agents in patients with hyperthyroidism or with an autonomously functioning thyroid nodule, suggest that this additional risk be evaluated before use of this drug. Iodine-containing contrast agents may alter the results of thyroid function tests which depend on iodine estimation, e.g., PBI, and may also affect results of radioactive iodine uptake studies. Such tests, if indicated, should be performed prior to the administration of this preparation.

PRECAUTIONS

Diagnostic procedures which involve the use of iodinated intravascular contrast agents should be carried out under the direction of personnel skilled and experienced in the particular procedure to be performed. All procedures utilizing contrast media carry a definite risk of producing adverse reactions. While most reactions are minor, life-threatening and fatal reactions may occur without warning, and this risk must be weighed against the benefit of the procedure. A fully equipped emergency cart, or equivalent supplies and equipment, and personnel competent in recognizing and treating adverse reactions of all types should always be available. If a serious reaction should occur, immediately discontinue administration. Since severe delayed reactions have been known to occur, emergency facilities and competent personnel should be available for at least 30 to 60 minutes after administration. (See ADVERSE REACTIONS.)

Preparatory dehydration is dangerous and may contribute to acute renal failure in infants, young children, the elderly, patients with pre-existing renal insufficiency, patients with multiple myeloma, patients with advanced vascular disease and diabetic patients.

Acute renal failure has been reported in diabetic patients with diabetic nephropathy and in susceptible non-diabetic patients (often elderly with pre-existing renal disease) following the administration of iodinated contrast agents. Therefore, careful consideration of the potential risks should be given before performing this radiographic procedure in these patients.

Severe reactions to contrast media often resemble allergic responses. This has prompted the use of several provocative pretesting methods, none of which can be relied on to predict severe reactions. No conclusive relationship between severe reactions and antigen-antibody reactions or other manifestations of allergy has been established. The possibility of an idiosyncratic reaction in patients who have previously received a contrast medium without ill effect should always be considered. Prior to the injection of any contrast medium, the patient should be questioned to obtain a medical history with emphasis on allergy and hypersensitivity. A positive history of bronchial asthma or allergy (including food), a family history of allergy, or a previous reaction or hypersensitivity to a contrast agent may imply a greater than usual risk. Such a history may be more accurate than pre-testing in predicting the potential for reaction, although not necessarily the severity or type of reaction in the individual case. A positive history of this type does not arbitrarily contraindicate the use of a contrast agent when a diagnostic procedure is thought essential, but does call for caution. (See ADVERSE REACTIONS.)

Prophylactic therapy including corticosteroids and antihistamines should be considered for patients who present with a strong allergic history, a previous reaction to a contrast medium, or a positive pre-test since in these patients the incidence of reaction is two to three times that of the general population. Adequate doses of corticosteroids should be started early enough prior to contrast medium injection to be effective and should continue through the time of injection and for 24 hours after injection. Antihistamines should be administered within 30 minutes of the contrast medium injection. Recent reports indicate that such pre-treatment does not prevent serious life-threatening reactions, but may reduce both their incidence and severity. A separate syringe should be used for these injections.

General anesthesia may be indicated in the performance of some procedures in selected patients; however, a higher incidence of adverse reactions has been reported in these patients, and may be attributable to the inability of the patient to identify untoward symptoms or to the hypotensive effect of anesthesia which can prolong the circulation time and increase the duration of contact of the contrast agent.

Angiography should be avoided whenever possible in patients with homocystinuria because of the risk of inducing thrombosis and embolism.

PRECAUTIONS FOR SPECIFIC PROCEDURES

Pediatric Angiocardiography: It is advisable to monitor for ECG and vital signs changes throughout the procedure.

When large individual doses are administered, sufficient time should be allowed for any observed changes to return to or near baseline prior to making the next injection.

Caution should be used when making right heart injections in patients with pulmonary hypertension or incipient heart failure, since this may lead to increased right side pressures with subsequent bradycardia and systemic hypotension. Patients with pulmonary disease present additional risks.

Caution is advised in cyanotic infants since apnea, bradycardia, other arrhythmias and a tendency to acidosis are more likely to occur.

Since infants are more likely to respond with convulsions than are adults, the amount of total dosage is of particular importance. Repeated injections are hazardous in infants weighing less than 7 kg, particularly when these infants have pre-existing compromised right heart function or obliterated pulmonary vascular beds.

Selective Coronary Arteriography with or without left ventriculography: During the administration of large doses of HEXABRIX, continuous monitoring of vital signs is desirable. Caution is advised in the administration of large volumes to patients with incipient heart failure because of the possibility of aggravating the pre-existing condition. Hypotension should be corrected promptly since it may result in serious arrhythmias.

Special care regarding dosage should be observed in patients with right ventricular failure, pulmonary hypertension, or stenotic pulmonary vascular beds because of hemodynamic changes which may occur after injection into the right heart outflow tract.

Peripheral Arteriography: Moderate decreases in blood pressure occur frequently with intra-arterial (brachial) injections. This change is usually transient and requires no treatment; however, the blood pressure should be monitored for approximately ten minutes following injection.

Extreme caution during injection of the contrast agent is necessary to avoid extravasation and fluoroscopy is recommended. This is especially important in patients with severe arterial disease.

Cerebral Angiography: Cerebral angiography should be performed with special caution in patients with advanced arteriosclerosis, severe hypertension, cardiac decompensation, senility, recent cerebral thrombosis or embolism, and migraine.

Intra-Arterial Digital Subtraction Angiography: The risks associated with IA-DSA are those usually attendant with catheter procedures. Following the procedure, gentle pressure hemostasis is required, followed by observation and immobilization of the limb for several hours to prevent hemorrhage from the site of arterial puncture.

Patient motion, including respiration and swallowing, can result in misregistration leading to image degradation and non-diagnostic studies.

Intravenous Digital Subtraction Angiography: The risks associated with IV-DSA include those usually attendant with catheter procedures and include intramural injections, vessel dissection and tissue extravasation. The potential risk is reduced when small test injections of contrast medium are made under fluoroscopic observation to insure that the catheter tip is properly positioned and, in the case of peripheral placement, that the vein is of adequate size.

Patient motion, including respiration and swallowing, can result in misregistration leading to image degradation and non-diagnostic studies.

Peripheral Venography: Special care is required when venography is performed in patients with suspected thrombosis, phlebitis, severe ischemic disease, local infection or a totally obstructed venous system.

Extreme caution during injection of contrast media is necessary to avoid extravasation and fluoroscopy is recommended. This is especially important in patients with severe arterial or venous disease.

Excretory Urography: Infants and small children should not have any fluid restrictions prior to excretory urography. (See WARNINGS and PRECAUTIONS concerning preparatory dehydration.)

Contrast Enhancement in Body Computed Tomography: Patient cooperation is essential since patient motion, including respiration, can markedly affect image quality. The use of an intravascular contrast medium can obscure tumors in patients undergoing CT evaluation of the liver, resulting in a false negative diagnosis. Dynamic CT scanning is the procedure of choice for malignant tumor enhancement.

Arthrography: Strict aseptic technique is required to prevent the introduction of infection. Fluoroscopic control should be used to insure proper introduction of the needle into the synovial space and prevent extracapsular injection. Aspiration of excessive synovial fluid will reduce the pain on injection and prevent the dilution of the contrast agent. It is important that undue pressure not be exerted during the injection.

Hysterosalpingography: Caution should be exercised in patients suspected of having cervical or tubal carcinoma to avoid possible spread of the lesion by the procedure. Delayed onset of pain and fever (1-2 days) may be indicative of pelvic infection.

Carcinogenesis, Mutagenesis, Impairment of Fertility: No long-term animal studies have been performed to evaluate carcinogenic potential. However, animal studies suggest that this drug is not mutagenic and does not affect fertility in males or females.

Pregnancy Category B: Reproduction studies have been performed in rats and rabbits at doses up to two times the maximum adult human dose and have revealed no evidence of impaired fertility or harm to the fetus due to HEXABRIX. There are, however, no adequate and well controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: Ioxaglate salts are excreted unchanged in human milk. Because of the potential for adverse effects in nursing infants, bottle feedings should be substituted for breast feedings for 24 hours following the administration of this drug.

Pediatric Use: Safety and effectiveness in children has been established in pediatric angiocardiography and intravenous excretory urography. Data have not been submitted to support the safety and effectiveness of HEXABRIX in any other indication. (Precautions for specific procedures receive comment under that procedure.)

ADVERSE REACTIONS

Adverse reactions to injectable contrast media fall into two categories: chemotoxic reactions and idiosyncratic reactions.

Chemotoxic reactions result from the physiochemical properties of the contrast media, the dose and the speed of injection. All hemodynamic disturbances and injuries to organs or vessels perfused by the contrast medium are included in this category.

Idiosyncratic reactions include all other reactions. They occur more frequently in patients 20 to 40 years old. Idiosyncratic reactions may or may not be dependent on the dose injected, the speed of injection, the mode of injection and the radiographic procedure. Idiosyncratic reactions are subdivided into minor, intermediate and severe. The minor reactions are self-limited and of short duration; the severe reactions are life-threatening and treatment is urgent and mandatory.

NOTE: Not all of the following adverse reactions have been reported with HEXABRIX. Because HEXABRIX is an iodinated intravascular contrast agent, all of the side effects and toxicity associated with agents of this class are theoretically possible, and this should be borne in mind when HEXABRIX is administered.

Severe: life-threatening anaphylactoid reactions, mostly of cardiovascular origin, have occurred following the administration of HEXABRIX as well as other iodine-containing contrast agents. Most deaths occur during injection or 5 to 10 minutes later; the main feature being cardiac arrest with cardiovascular disease as the main aggravating factor. Isolated reports of hypotensive collapse and shock are found in the literature. Based upon clinical literature, reported deaths from the administration of conventional iodinated contrast agents range from 6.6 per 1 million (0.00066 percent) to 1 in 10,000 patients (0.01 percent).

Regardless of the contrast agent employed, the overall estimated incidence of serious adverse reactions is higher with coronary arteriography than with other procedures. Cardiac decompensation, serious arrhythmias, or myocardial ischemia or infarction may occur during coronary arteriography and left ventriculography.

The most frequent adverse reactions are nausea, vomiting, facial flush and a feeling of body warmth. These are usually of brief duration. In double-blind clinical trials, HEXABRIX produced less discomfort upon injection (pain and heat) when compared to various other contrast agents. Other reactions include the following:

Hypersensitivity reactions: Dermal manifestations of urticaria with or without pruritus, erythema and maculopapular rash. Dry mouth. Sweating. Conjunctival symptoms. Facial, peripheral and angioneurotic edema. Symptoms related to the respiratory system include sneezing, nasal stuffiness, coughing, choking, dyspnea, chest tightness and wheezing, which may be initial manifestations of more severe and infrequent reactions including asthmatic attack, laryngospasm and bronchospasm with or without edema, pulmonary edema, apnea and cyanosis. Rarely, these allergic-type reactions can progress into anaphylaxis with loss of consciousness, coma, severe cardiovascular disturbances, and death.

Cardiovascular reactions: Generalized vasodilation, flushing and venospasm. Occasionally thrombosis or, rarely, thrombophlebitis. Extremely rare cases of disseminated intravascular coagulation resulting in death have been reported. Severe cardiovascular responses include rare cases of hypotensive shock, coronary insufficiency, cardiac arrhythmia, fibrillation and arrest. These severe reactions are usually reversible with prompt and appropriate management; however, fatalities have occurred.

Technique reactions: Extravasation with burning pain, hematomas, ecchymosis and tissue necrosis, vascular constriction due to injection rate, thrombosis and thrombophlebitis.

Neurological reactions: Spasm, convulsions, aphasia, syncope, paresis, paralysis resulting from spinal cord injury and pathology associated with the syndrome of transverse myelitis, visual field losses which are usually transient but may be permanent, coma and death.

Other reactions: Headache, trembling, shaking, chills without fever, hyperthermia and lightheadedness. Temporary renal shutdown or other nephropathy.

Pediatric angiocardiography has been complicated by intramural injection with marked adverse effects on cardiac function.

During selective coronary arteriography with or without left ventriculography, patients may have clinically insignificant ECG changes. The following adverse effects have occurred in conjunction with the administration of iodinated intravascular contrast agents for this procedure: hypotension, shock, anginal pain, myocardial infarction, cardiac arrhythmias (bradycardia, ventricular tachycardia, ventricular fibrillation) and cardiac arrest. Fatalities have been reported. Complications to the procedure include dissection of coronary arteries, dislodgement of atheromatous plaques, perforation, hemorrhage and thrombosis.

Following peripheral arteriography, hemorrhage and thrombosis have occurred at the puncture site of the percutaneous injection. Brachial plexus injury has been reported following axillary artery injection.

The major causes of cerebral arteriographic adverse reactions appear to be repeated injections of the contrast material, administration of doses higher than those recommended, the presence of occlusive atherosclerotic vascular disease and the method and technique of injection. Adverse reactions are normally mild and transient. A feeling of warmth in the face and neck is frequently experienced. Infrequently, a more severe burning discomfort is observed. Transient visual hallucinations have been reported. Serious neurological reactions that have been associated with cerebral angiography and not listed under Adverse Reactions include stroke, amnesia and respiratory difficulties. Visual field defects with anopsia and reversible neurological deficit lasting from 24 hours to 48 hours have been reported. Confusion, disorientation with hallucination, and absence of vision sometimes lasting for one week have also been reported. Cardiovascular reactions that may occur with some frequency are bradycardia and either an increase or decrease in systemic blood pressure. The blood pressure change is transient and usually requires no treatment. Arthrography may induce joint pain or discomfort which is usually mild and transient but occasionally may be severe and persist for 24 to 48 hours following the procedure. Effusion requiring aspiration may occur in patients with rheumatoid arthritis. Fever and pain, cramping and tenderness of the abdomen have been reported following hysterosalpingography.

OVERDOSAGE

Overdosages may occur. The adverse effects of overdosage are life-threatening and affect mainly the pulmonary and cardiovascular systems. The symptoms may include cyanosis, bradycardia, acidosis, pulmonary hemorrhage, convulsions, coma and cardiac arrest. Treatment of an overdose is directed toward the support of all vital functions and prompt institution of symptomatic therapy.

Ioxaglate salts are dialyzable.

The intravenous LD_{50} values of HEXABRIX (in grams of iodine/kilogram body weight) were 11.2 g/kg in mice, >8 g/kg in rats, >6.4 g/kg in rabbits and >10.2 g/kg in dogs.

DOSAGE AND ADMINISTRATION

Details on dosage are provided in the package insert.

QRS Morphology-Dependent Pharmacodynamics in Multiform Ventricular Ectopic Activity

KENNETH M. KESSLER, MD, DANEIL McAULIFFE, RN, PATRICIA KOZLOVSKIS, PhD, RICHARD G. TROHMAN, MD, LIAQAT ZAMAN, MD, AGUSTIN CASTELLANOS, MD, RAFAEL SEQUEIRA, MD, and ROBERT J. MYERBURG, MD

The effect of an infusion of intravenous procainamide on the frequency of ventricular premature complexes (VCPs) of differing QRS morphologies was studied in 20 patients with multiform ectopic activity. In 17 of 20 patients, there was differential suppression of single VPCs with different QRS morphologies. VPCs of the most frequent QRS morphology and the second most frequent QRS morphology were compared with respect to the procainamide level at the escape of VPCs from 85% suppression and the duration of suppression measured from the onset of the procainamide infusion. In 8 patients, VPCs of the most frequent QRS morphology remained suppressed at lower procainamide concentrations and for longer times than did VPCs of the second most frequent QRS morphology (escape procainamide concentration = 2.8 ± 1.7 versus 5.4 ± 2.3 μg/ml, p <0.025; time to escape 244 ± 138 versus 98 ± 114 min; p <0.05). In 9 other patients, VPCs of the second most frequent QRS morphology remained suppressed at lower procainamide concentrations and for longer times than did VPCs of the most frequent QRS morphology (escape procainamide concentration 2.9 ± 1.4 versus 8.3 ± 6.3 μg/ml, p <0.025; time to escape 317 ± 114 versus 63 ± 80 min; p <0.001). Thus, in individual patients there are specific patterns of suppression of VPCs of different QRS morphologies which are independent of the frequency of each morphology. There is apparently a differential pharmacologic effect of procainamide on the foci or pathways responsible for the different QRS morphologies of multiform VPCs.

(Am J Cardiol 1988;61:563–569)

Both total frequency of ventricular premature complexes (VPCs) and occurrence of specific high-risk forms of ventricular ectopic activity have been used to estimate the risk of potentially lethal ventricular arrhythmias and sudden death.[1-9] Pharmacodynamic studies designed to evaluate the effect of drugs on ventricular ectopic activity and the alteration of risk of potentially lethal arrhythmias are limited. Quantitative suppression of ectopic activity is a goal that may be difficult to achieve,[7,10] and suppression of salvos or nonsustained ventricular tachycardia may be a better therapeutic endpoint in the highest risk groups. The information available on intermediate forms of complex ventricular arrhythmias, such as multiform complexes, is even more limited. It has been suggested that multiform VPCs constitute a risk category intermediate between frequent unifocal VPCs and salvos of 3 or more beats in postmyocardial infarction patients.[11] However, no data are available on the pharmacodynamic responses of multiform VPCs in general or the response of VPCs of different QRS configurations in particular. The present study was designed to evaluate the relation between plasma levels of a model antiarrhythmic agent, procainamide, and the suppression of VPCs of different QRS morphologies in patients experiencing multiform ventricular ectopic activity.

≥85% suppression for 30 minutes in 5 of 80 = 6.25%; ≥95% suppression for 30 minutes in 1 of 80 = 1.25%; ≥ 85% suppression for 60 minutes in 0 of 80 = 0.00%. Criteria for escape of PVCs: Return of >5% or >15% of PVCs for 1 or 2 half-hour intervals, respectively.

0 = either no decrease or an increase in PVCs.

* ≥85% suppression.

Methods

Patient selection: Twenty patients admitted to the coronary care or telemetry units were studied. Entry criteria included: (1) multiform VPCs (see definition later); (2) no contraindication to therapy with a class I antiarrhythmic agent; and (3) no antiarrhythmic agent administered for the preceding 48 hours (or >5 drug half-lives). The history and physical examination were reviewed in detail with specific reference to the cardiovascular diagnosis and presence of transient arrhythmogenic factors (e.g., acute ischemia, hypoxia, hypokalemia, aminophylline use). Patients had a clinical indication for antiarrhythmic therapy and informed consents were obtained from each. All were at steady state and no changes in therapy were instituted during the study protocol.

Treatment protocol: A 2-channel ambulatory monitor was used to record continuous rhythm data before, during and after antiarrhythmic intervention. After a 2-hour baseline recording, procainamide hydrochloride was infused intravenously (25 mg/min) to 1 of the following endpoints: (1) 100 mg more than the dose required for 100% VPC suppression or (2) 1,000 mg total dose. In no case was dosing limited due to toxicity (e.g., hypotension, QRS prolongation or proarrhythmic effect). Blood samples were obtained for procainamide and N-acetyl procainamide concentrations at baseline and hourly after the onset of drug administration for 6 to 8 hours. Longer baseline observations, although preferable, were deemed clinically inappropriate because a need to treat had been determined.

Analysis of arrhythmia recordings: Ambulatory recordings were made on a 2-channel recorder and

transcribed using a computerized system (Del-Mar Avionic Heart Screen II). The initial analysis was semiautomated, with preselection of counting criteria done by 1 or more of the authors experienced in arrhythmia interpretation and monitoring techniques; extensive real-time counting was necessary. The frequency of VPCs of each QRS morphology subset was counted and logged by half-hour intervals. The characterization of VPC-QRS morphologies required identical QRS configuration in both monitor leads as determined by the Del-Mar algorithm and confirmed by visual inspection. Pharmacodynamic data were analyzed for VPCs of the most frequent and second most frequent QRS morphologies.

Antiarrhythmic drug analysis: All blood samples were transferred promptly to our research laboratory and centrifuged. Albumin was quantitated by a commercial kit (SIGMA Chemical Co.). Procainamide and N-acetyl procainamide were quantitated by gas-liquid chromatography using a nitrogen-phosphorous selective detector (Hewlett-Packard 5710A).[12] The standard error of the estimate for this technique is <5% of the determined value.

Statistical analysis: Definitions used for the statistical modeling of the pharmacodynamic data included: (1) *baseline frequency*, defined as the average number of VPCs during the 4 half-hour predrug baseline recording intervals; (2) *time to escape*, referred to reemergence of ventricular ectopic activity after suppression by procainamide. It was defined as the time in minutes from the onset of the procainamide infusion until the frequency of suppressed VPCs exceeded 15% of the baseline frequency for 2 consecutive half-hour intervals, i.e., suppression falling below 85% (see validation of suppression criteria in the Results section); (3) *concentration at escape*, defined as the plasma concentration of procainamide at the time to escape, extrapolated from the plasma concentration curve; (4) *differential suppression* (i.e., QRS-morphology dependent pharmacodynamics), when the time to escape of the 2 VPCs having different QRS morphologies varied by at least 2 half-hour intervals. Student *t* tests were used to compare group characteristics. Statistical significance was assigned to the $p < 0.05$ level.

Results

Demographic data: There were 17 men and 3 women, mean age 63 ± 12 years. Primary diagnoses included chronic coronary artery disease in 9 patients, idiopathic dilated cardiomyopathy in 5 and acute myocardial infarction in 4. Acute or chronic congestive heart failure complicated the course in 12 of 20 patients. Six had had symptomatic ventricular tachycardia by history. Mean ejection fraction was 32 ± 16%, mean weight 77 ± 13 kg, mean albumin 4.2 ± 0.7 g%, and mean creatinine 1.2 ± 0.5 mg% (Table I).

Validation of suppression criteria: Suppression criteria were derived from prospective analysis of the trends in spontaneous variability of VPCs of the most frequent and second most frequent QRS morphologies during the 2-hour predrug, baseline phase. The predrug period was divided into 4 half-hour intervals and the frequency of VPCs of the most frequent and second most frequent QRS morphology in the third and fourth intervals was compared to the average of the first and second half-hour intervals. A spontaneous decrease of VPC frequency of >85% was observed in only 5 (6.25%) of 80 comparisons (Table II), and the incidence of spontaneous decrease of >95% was only 1.25%. A >85% reduction for both 30-minute intervals was never recorded. Thus, although spontaneous variability was evident, the probability of observing a false positive decrease of VPCs in any 1 half-hour interval was low (and inconsequential when either >85% suppression for 2 continuous half-hour intervals or >95% suppression was considered). On the basis of this observation, the criteria for significant VPC suppression in our patient group was defined as a >85% decrease in VPCs for 2 or more half-hour intervals, or >95% decrease in VPCs for 1 half-hour interval. Conversely, escape of ectopic activity following procainamide suppression study was defined as a return of ectopy to >15% of baseline VPC frequency for 2 half-hour intervals.

Baseline arrhythmia characteristics: Entry criteria required each patient to have 2 or more VPC-QRS morphologies identified on 2-channel full-disclosure ambulatory monitor recordings. There were 2 morphologies in 11 patients, 3 morphologies in 3, 4 morphologies in 3 and 5 or more morphologies in 3 (Table III). However, the 2 most frequent QRS morphologies accounted for >90% of all VPCs in 18 of 20 patients; therefore, only VPCs of the first and second most frequent QRS morphologies were analyzed. The baseline frequency of VPCs of the most frequent QRS morphology averaged 154 ± 148 per hour and of the second most frequent QRS morphology 38 ± 49 per hour. Repetitive forms of >2 VPCs were present in 19 of 20 patients and most frequently were of mixed QRS configurations (Table III).

Pharmacokinetic data: The mean procainamide loading dose was 943 ± 109 mg, with 15 of 20 patients receiving 1,000 mg (Table IV). Peak procainamide concentrations were highly variable, ranging from 5.5 to 24.4 μg/ml. The calculated mean plasma half-life (2.9 ± 0.8 hours), total body clearance (7.3 ± 2.3 ml/min/kg), and apparent steady state volume of distribution (1.8 ± 0.4 liter/kg) were normal. Variations in volume of distribution accounted for only 43% ($r = 0.66$) of the variability in peak levels. Procainamide binding was normal in each patient (60 to 70% unbound fraction). N-acetyl procainamide values were all well below the "therapeutic" range and were not considered in data management (Table IV). The difference in the time to escape of VPCs of the most frequent and second most frequent QRS morphologies was in part related to procainamide half-life ($r = 0.46$, $p < 0.05$).

Pharmacodynamic data of single ventricular premature complexes: Differential suppression of VPCs of the most frequent and second most frequent QRS morphologies was observed in 17 of 20 (85%) patients (Table III). In 8 patients, VPCs of the most frequent QRS morphology (baseline frequency 278 ± 218/hour) were suppressed at a lower procainamide concentration (mean escape concentration 2.8 ± 1.7 μg/ml) and for a longer period of time (mean time to escape 244 ±

M_1 = VPCs of the most frequent QRS morphology; M_2 = VPCs of the second most frequent QRS morphology; M = repetitive forms of VPCs of mixed (multiform) QRS morphologies; SD = standard deviation; U = repetitive forms of VPCs of uniform QRS morphologies.

138 minutes) than were VPCs of the second most frequent QRS morphology, with baseline frequency 52 ± 50 premature ventricular contractions/hour, mean escape contration of procainamide 5.4 ± 2.3 μg/ml ($p < 0.025$) and mean time to escape 98 ± 114 minutes ($p < 0.05$). Figure 1 shows the percent suppression of VPCs of the most frequent and second most frequent QRS morphologies as a function of procainamide concentrations. In this example, VPCs of the most frequent morphology were more easily and completely suppressed.

In 9 patients, VPCs of the second most frequent QRS morphology (baseline frequency 106 ± 178 VPC/hour) were suppressed at a lower concentration of procainamide (mean escape concentration 2.9 ± 1.4 μg/ml) and for a longer time (mean time to escape 317 ± 114 minutes) than were VPCs of the most frequent QRS morphology, with baseline frequency 400 ± 376 VPC/hour, mean escape concentration of procainamide 8.3 ± 6.3 μg/ml ($p < 0.025$) and mean time to escape 63 ± 80 minutes ($p < 0.001$). Figure 2 shows such a pattern of differential suppression, whereas Figure 3 demonstrates a differential effect without suppression and an apparent increase in the number of VPCs of the most frequent QRS morphology, and at the same time a significant suppression of VPCs of the second most frequent QRS morphology. In 3 patients, there were no differences in the pharmacodynamics of single VPCs of the most frequent and second most frequent QRS morphologies.

Discussion

To study the pharmacodynamics of simple and complex forms of ventricular arrhythmias, both theoretical considerations and empiric observations led us

to design this prospective study using multiform ventricular ectopic activity as a model.

Multiform ventricular ectopic activity occupies a central position in the ventricular arrhythmia complexity schema and multiform ectopic activity is frequently associated with repetitive forms.[13–15] However, initiation of the study was hampered by the lack of intrinsic information on the pharmacodynamics of multiform VPCs. Prior studies had grouped multiform VPCs with other complex forms[2–4,8,16,17] and there was a systematic underestimation of multiformity established by reporting only the highest grade of ventricular ectopic activity. Thus, the reported prevalence of multiform VPCs varied from 2%[2] to 92%[16] in high-risk patients. Furthermore, there was disagreement as to the clinical importance of multiformity per se, with some studies supporting multiform VPCs as a risk factor for malignant ventricular arrhythmias or cardiac mortality, or both,[3,5,8,17] while others did not support such a risk.[2] Finally, the mechanism of multiformity also remains undefined. Multiformity may result from either multiple sites of origin (multifocality) or variable exit sites or pathways from the same focus or reentrant circuit. Different sites or different exit pathways may exhibit similar or contrasting responses to pharmacologic intervention. Potentially, clinically important arrhythmias might be suppressed concurrently with suppression of 1 morphology, but not the other(s), and suppression could dissociate from total VPC suppression.

Pharmacodynamic and pharmacokinetic implications: The current study shows that the pharmacodynamic response often differs between the 2 most fre-

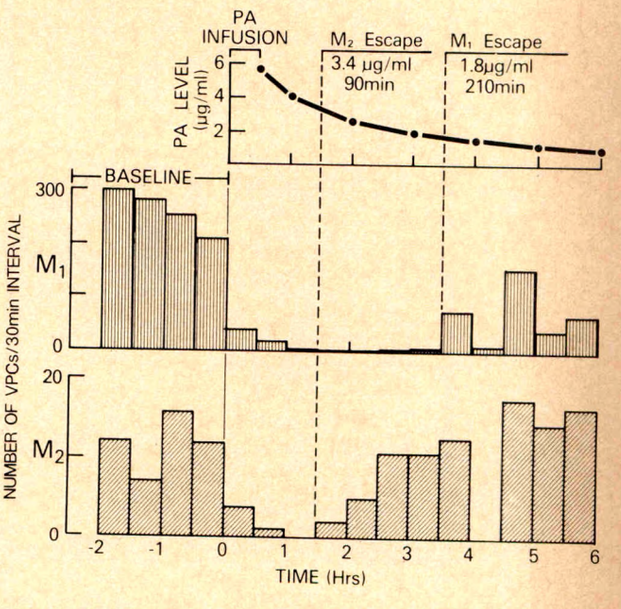

FIGURE 1. Differential suppression of ventricular premature complexes (M1 > M2 sensitivity). The number of ventricular premature complexes (VPCs) of the most frequent (M1) and second most frequent (M2) QRS morphologies is plotted along with simultaneous procainamide (PA) levels for patient 1. VPCs of the most frequent (M1) QRS morphology (mean baseline frequency 534/hour) were suppressed for a longer time (210 minutes) and to a lower procainamide concentration (1.8 μg/ml) than were VPCs of the second most frequent (M2) QRS morphology (mean baseline frequency 24/hour), which suppressed for only 90 minutes and required a procainamide concentration of 3.4 μg/ml for suppression.

quent single VPC-QRS morphologies of multiform pattern. Most of the patients (18 of 20) had organic heart disease, with 6 of 20 previously manifesting life-threatening ventricular arrhythmia. VPCs of >2 QRS morphologies were present in 45% of patients but only 15% of patients had >5 QRS morphologies. The overall VPC frequency was well in excess of the risk threshold of >10/hour suggested for patients with recent myocardial infarction.[18] Morphology-dependent suppression of VPCs was demonstrated in 85% of the patients. Differential suppression favors multiple reentrant circuits or foci rather than variable exits from the same circuit or focus as the mechanism for multiformity in these patients. Suppression of VPCs of the more sensitive QRS morphology occurred at a mean procainamide concentration below the "therapeutic range" (2.9 ± 1.6 μg/ml), whereas the less sensitive form often was not suppressed at procainamide concentrations in the high therapeutic to supra-therapeutic range. The time differential regarding the escape of the 2 morphologies varied from our minimum definition for differential suppression of 60 minutes to greater than 390 minutes and was in part a function of drug half-life. Thus, the occurrence and degree of differential suppression related both to the absolute procainamide concentration achieved and to the rate of decrease during the distribution and elimination phases, implying that the pharmacodynamics of differential suppression might vary as a function of both electropharmacologic and pharmacokinetic parameters in a given individual.

Therapeutic implications: VPCs with varying pharmacodynamic responses to therapy may coexist and there is no therapeutic continuum with respect to ventricular ectopic activity. Such information complements previous data showing differential therapeutic responses of complex and single ectopy as well as differential thresholds for the suppression of VPCs based on clinical setting.[10] The current data suggest that should concordance be established between the suppression of single VPCs and repetitive forms initiated by ventricular complexes of a similar QRS morphology, suppression of specific VPCs may provide individualization of therapy targeted to high-risk tachycardias. When suppression is via VPCs of the less frequent QRS morphology, repetitive form suppression will become independent of statistically significant[19] suppression of total VPCs. Indeed, selective suppression of premature ventricular contraction subsets provides 1 mechanism whereby a high degree of single premature ventricular contraction suppression may not be needed to suppress repetitive forms in selected patients. We conclude that the foci or pathways re-

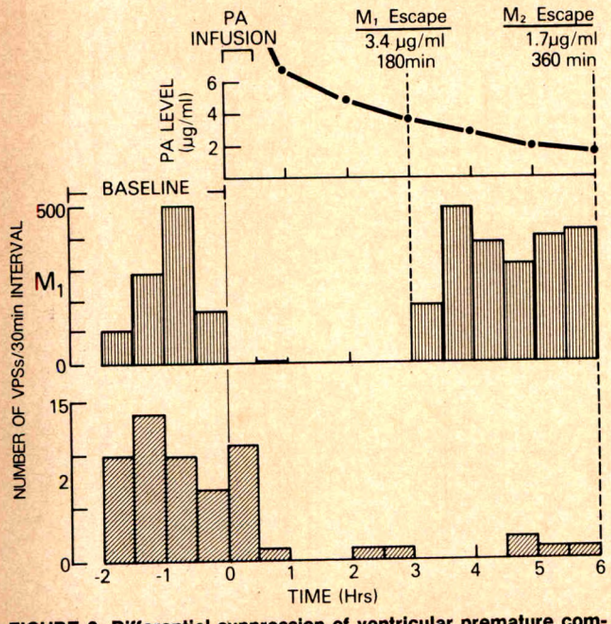

FIGURE 2. Differential suppression of ventricular premature complexes (M2 > M1 sensitivity). The number of ventricular premature complexes (VPC) of the most frequent (M1) and second most frequent (M2) QRS morphologies is plotted along with simultaneous procainamide (PA) levels for patient 18. VPCs of the second most frequent QRS morphology (mean baseline frequency 532/hour) were suppressed for a longer time (>360 minutes) and to a lower procainamide concentration (<1.7 μg/ml) than VPCs of the most frequent (M1) QRS morphology (mean baseline frequency 20/hour), which suppressed for 180 minutes and required a procainamide concentration of 3.4 μg/ml for suppression.

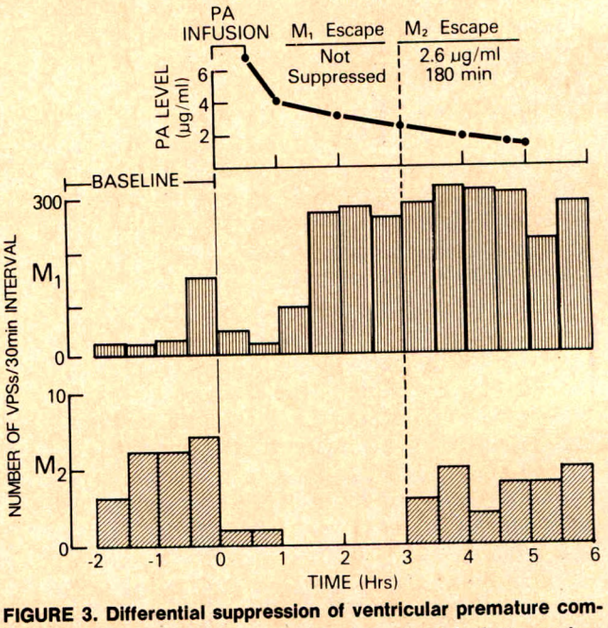

FIGURE 3. Differential suppression of ventricular premature complexes (M2 > M1 sensitivity). The number of ventricular premature complexes (VPC) of the most frequent (M1) and second most frequent (M2) QRS morphologies is plotted along with simultaneous procainamide (PA) levels for patient 9. VPCs of the second most frequent QRS morphology (mean baseline frequency 12/hour) were suppressed for 180 minutes to a procainamide level of 2.6 μg/ml. VPCs of the most frequent QRS morphology (mean baseline frequency 116/hour) showed an increase in frequency after the procainamide infusion (average 526 VPCs/hour from 1 to 6 hours after drug infusion).

sponsible for VPCs of different QRS morphologies appear to have different responses to pharmacologic intervention and that this may relate to endpoints of therapy.

Tocainide Plus Quinidine for Treatment of Ventricular Arrhythmias

JEAN T. BARBEY, MD, KATHERINE A. THOMPSON, MD, DEBRA S. ECHT, MD, RAYMOND L. WOOSLEY MD, PhD, and DAN M. RODEN, MD

Tocainide and quinidine were administered both as single agents and in combination to 14 patients with chronic ventricular arrhythmias. Therapy with tocainide was limited by the occurrence of dose-related adverse reactions in 8 patients, but could be titrated to a dose that was well-tolerated in 13 of 14 and effective in 2 of 13. The addition of quinidine gluconate to the tolerated dose of tocainide increased the number of patients with arrhythmia suppression from 2 to 6. After tocainide washout, quinidine alone suppressed arrhythmias in only 3 patients. Analysis of electrocardiogram intervals showed that the drugs had additive effects on the coupling interval of the sinus beat to the predominant ectopic beat, but exerted antagonistic effects on the corrected QT interval. These findings suggest that the combination may be clinically useful, exerting pharmacologic effects unlike either agent alone.

(Am J Cardiol 1988;61:570–573)

Antiarrhythmic therapy with single agents is frequently only moderately effective and can be limited by the occurrence of adverse effects related to plasma concentrations.[1] Therefore, the strategy of combining drugs to keep doses under those associated with side effects, yet maintain or even increase efficacy, has been advocated. In guinea pig ventricular papillary muscle preparations, Hondeghem and Katzung[2] showed that the combination of lidocaine and quinidine produced supra-additive effects on the $\dot{V}_{max}$ of early extrasystoles but an effect no different from quinidine alone on normal complexes. These data suggested that such combinations might suppress closely coupled abnormal beats while exerting little effect on sodium channels of normal beats. In a group of patients with ventricular arrhythmias, we found that the combination of quinidine and the lidocaine analog mexiletine was more effective and less likely to cause side effects than therapy with either agent alone.[3]

Tocainide, like mexiletine, is a lidocaine analog which can be used orally. In vitro, it blocks the fast inward sodium current and shortens action potential duration.[4] Treatment with tocainide is frequently limited by dose-related neurologic side effects such as tremor or ataxia.[5] Although tocainide and mexiletine produce similar electrophysiologic changes and have comparable side effect profiles, reports from our group and others have suggested that response to 1 lidocaine analog is not predictive of response to the other.[6–8] Tocainide is currently prescribed as a racemic mixture. Of the 2 stereoisomers, the R(−) form is more potent in suppressing arrhythmias in an animal model[9]; however, its plasma concentrations are usually lower than those of the S(+) stereoisomer during tocainide administration in man.[10]

Quinidine also blocks cardiac sodium channels but prolongs the duration of the action potential in most tissues.[11] As with tocainide therapy, side effects during quinidine are frequent and range from diarrhea to arrhythmia aggravation.[12] This study determines if the addition of a low dose of quinidine to tocainide could enhance the efficacy and decrease the toxicity of tocainide given alone and characterizes the antiarrhythmic, pharmacokinetic and electrocardiographic features of this combination.

Methods

Adults with >30 ventricular premature complexes (VPCs) per hour over at least 48 hours of ambulatory electrocardiograph recordings were candidates for this trial. Patients with recent myocardial infarction, symptomatic sinus node dysfunction, abnormal conduction or supraventricular arrhythmias were excluded. Tocainide hydrochloride in 400 or 600 mg tablets, quinidine gluconate in 324 mg tablets and identical placebos (all supplied by Merck, Sharp and Dohme) were administered at 8-hour intervals throughout the study.

Study design: Patients were admitted to the Clinical Research Center where, under continuous electrocardiographic monitoring, their antiarrhythmic drug therapies were stopped. After stabilization of arrhythmia frequency with no treatment (and at least 4 elimination half-lives after discontinuation of therapy), placebo administration was begun. Patients whose arrhythmia frequency met entry criteria on placebo continued participating during the rest of the study. There were 4 phases following the placebo run-in, each with a 3-day duration: (1) tocainide 400 mg every 8 hours for each patient; (2) tocainide dose adjustment; (3) treatment with the most effective well-tolerated dosage of tocainide plus 324 mg of quinidine gluconate every 8 hours; and (4) tocainide washout on this dose of quinidine alone.

During the tocainide adjustment phase, the drug was increased to 600 mg every 8 hours if arrhythmias were not suppressed and side effects were absent, or decreased to 200 mg every 8 hours if side effects were present. On the third day of each treatment phase, arrhythmia frequency was quantified by 24-hour ambulatory electrocardiography. The electrocardiogram intervals were measured from a 12-lead recording and trough plasma samples were collected. Quinidine plasma concentrations were determined by reverse-phase high-pressure liquid chromatography. A stereospecific gas chromatographic procedure was used to measure concentrations of the R(−) and S(+) stereoisomers of tocainide.

Data analysis: All data are expressed as mean ± standard deviation. Arrhythmias were considered suppressed if ≥70% of total VPCs and ≥95% of runs (defined as ≥3 consecutive VPCs) were abolished. Student *t* test for paired data or 2-way analysis of variance for multiple observations were used to analyze changes during the course of the study with a p value <0.05 required to reject the null hypothesis of equal means. VPC counts were log-transformed prior to analysis. If significant differences among means were detected by analysis of variance, Duncan's test was used for pairwise comparisons.

Results

Patient characteristics: Eleven of the 14 patients who participated in this study were males. Mean age was 60 ± 9 years and left ventricular ejection fraction 35 ± 13%. Seven patients had coronary artery disease, 6 cardiomyopathy and 1 congenital heart disease. The median number of VEDs/hour was 258 (range 69 to 2,361). Runs were present in 12 patients, but occurred more frequently than 1 per hour in only 3. The average number of previously failed antiarrhythmic trials was 2.5 ± 1 per patient; in all 14 patients, a history was elicited that quinidine and procainamide had been ineffective.

Efficacy: Of the 10 patients who completed all 4 phases of the study as described above, only 2 had arrhythmia suppression after a well-tolerated dose of tocainide alone (1,200 mg/day in 1 case, 1,800 mg/day in the other). Addition of quinidine to this same dose of tocainide also suppressed VPCs in these 2 patients as well as in 4 others. After tocainide washout, 3 patients maintained arrhythmia control on quinidine alone, including the 2 in whom a well-tolerated dose of tocainide alone had been effective previously. Three patients could not complete the study because of intolerable side effects (quinidine-related in 2, tocainide-related in 1). The 14th patient received a lower dose of tocainide during concomitant quinidine therapy than during the titration phase because of neurologic side effects attributed to tocainide. VPC counts were significantly reduced by all 3 drug treatments from baseline ($p < 0.01$, analysis of variance), and counts during tocainide and during tocainide and quinidine were significantly less than during low-dose quinidine.

Adverse reactions: Seven of the 14 patients who received therapy with tocainide alone developed neurologic side effects that resolved with decreased dosage. One patient could not complete the study because of abdominal pain which improved only when tocainide was discontinued entirely. Four patients developed side effects while receiving combination therapy. These adverse effects persisted on quinidine alone after tocainide washout in 3 patients.

Plasma drug concentrations: Plasma concentrations associated with efficacy during therapy with tocainide alone (n = 2) were 5.5 and 8.5 μg/ml for total tocainide, 1.3 and 2.6 μg/ml for R(−) tocainide and 4.3 and 5.9 μg/ml for the S(+) isomer. During combination therapy, effective plasma concentrations (n = 6) ranged from 2.8 to 12.9 for total tocainide, 1.0 to 2.7 μg/ml for R(−) tocainide and 1.8 to 7.1 for the S(+) isomer. Low concentrations of S(+) tocainide were present in the plasma of 8 patients at the end of the tocainide washout period. Mean plasma quinidine concentration (Figure 1) after 3 days of treatment rose from 1.5 ± 0.5 μg/ml to 1.9 ± 0.8 μg/ml ($p < 0.05$), 3 days after tocainide withdrawal. On the other hand, there was no significant effect of quinidine on mean plasma tocainide concentration or on the ratio of S(+) to R(−) isomers, which ranged from 1.4 to 5.6.

Changes in electrocardiographic intervals: Therapy with a well-tolerated dose of tocainide shortened the QTc interval significantly compared to baseline ($p < 0.05$). QTc increase during quinidine alone after tocainide withdrawal was also significant ($p < 0.05$), compared to baseline and tocainide values (Figure 2). QRS was unchanged during the study. In contrast to these findings, the coupling interval of sinus beat to the predominant ectopic beat, a potential index of drug

effect on sodium channels[2,3] which was assessable in 6 patients, was significantly prolonged (compared to baseline) only during combination therapy (Figure 3, $p < 0.01$, analysis of variance). Thus, single-agent treatment shortened (tocainide) or prolonged (quinidine) repolarization, whereas sinus-ectopic coupling tended to increase with all treatments and particularly with the combination.

Discussion

Tocainide alone was effective in only 2 of 14 patients participating in this study, whereas quinidine alone was effective in 3. Addition of low-dose quinidine to a tolerated dose of tocainide suppressed arrhythmias in 6 of 13 patients. Moreover, the margin between tocainide plasma concentrations associated with efficacy and those associated with side effects was increased by the addition of quinidine (Figure 4). In this study, the combination was the only effective treatment arm in 3 of 6 patients. Response to higher doses of quinidine was not evaluated as part of this protocol, but these patients had been referred to our institution because of ventricular arrhythmias resistant to quinidine and procainamide. We conclude that the combination of quinidine and tocainide may, in certain cases, be more efficacious than higher doses of

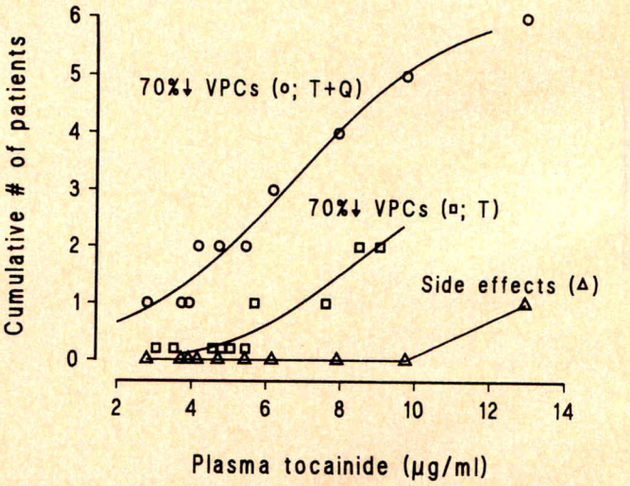

FIGURE 4. Relation between plasma tocainide and cumulative number of patients responding with 70% suppression of ventricular ectopic depolarizations (VPCs) during combined treatment (*open circles*, T + Q) and during tocainide (*squares*, T), as well as those developing side effects during tocainide (*triangles*). Data are shown from the 10 patients completing all 4 treatment arms. The addition of quinidine to tocainide widened the margin between tocainide concentrations associated with efficacy and with toxicity.

either agent alone. Our findings are similar to those reported by Kim et al,[13] who found enhanced efficacy and reduced side effects with the combination in patients with frequent VPCs. In contrast to our study, their design permitted dosage adjustment of either drug at the investigator's discretion at 2-day intervals. They did not report any plasma concentration data and, contrary to our findings discussed later, they detected QRS widening caused by the combination and did not report sinus-ectopic beat coupling interval data.

Plasma quinidine concentrations were slightly higher after tocainide withdrawal than they had been during combination therapy. The explanation for this finding, which requires confirmation, is not known. One possibility is that the rise merely reflected gradual attainment of steady state plasma concentrations between days 3 and 6 of quinidine treatment (although quinidine's elimination half-life of 4 to 16 hours[14] suggests that steady state conditions were indeed present by day 3). The other possibility is that tocainide increased the clearance or the volume of distribution of quinidine by yet unidefined mechanisms. Whatever the interaction mechanism, it did not account for the combination's enhanced efficacy because plasma quinidine concentrations were in fact lower during combination treatment. As previously reported by others,[5] plasma concentration of the S(+) isomer was greater than that of the R(−) isomer in all samples collected. The study design, however, does not allow conclusions to be drawn about the relative contribution of each isomer to the efficacy or the toxicity of tocainide.

Analysis of the electrocardiographic intervals suggests 2 electrophysiologic effects accompanying the increased antiarrhythmic activity noted during combination therapy. At baseline, single morphology VPCs with fixed coupling were present in 6 patients. The combination therapy prolonged this coupling interval to a greater extent than did either agent alone, presumably reflecting an additive effect of the drugs' sodium channel blocking properties. As pointed out by others,[2] the combination of quinidine and lidocaine is particularly attractive because of its potential for greater antiarrhythmic effects at short coupling intervals (or rapid rates) and minimal effect on baseline electrophysiology. Moreover, quinidine's prolonging effect on action potential increases the time sodium channels spend in the inactivated state, thereby theoretically enhancing sodium current depression by drugs which block inactivated channels (such as lidocaine).[15]

In contrast to this additive action on sinus-ectopic coupling, QTc duration measured during combination therapy was found to be intermediate between those observed during treatment with either agent alone. Kim et al[13] also found additive sodium channel effects (QRS widening) and antagonistic QTc effects. Tocainide, by limiting the quinidine-induced prolongation of repolarization, may increase the ratio of the ventricular effective refractory period to the duration of action potential, an effect thought to correlate with antiarrhythmic activity.[16] Thus, electrocardiographic indexes suggest that the favorable interaction noted between quinidine and tocainide has an underlying electrophysiologic basis similar to the previously described quinidine-mexiletine association.[2,3] These effects may account for the enhanced efficacy at tolerated dosages seen with the combinations.

Termination of Sustained Ventricular Tachycardia by External Noninvasive Pacing

JERRY C. LUCK, MD, BLAIR P. GRUBB, MD, STEPHEN E. ARTMAN, CCVT, ROBERT T. STECKBECK, RN, and MICHAEL L. MARKEL, MD

Cardiac pacing has proven useful in the termination of sustained ventricular tachycardia (VT). In this study, the effectiveness of external noninvasive temporary pacing was compared with traditional endocardial burst ventricular pacing for the termination of sustained and hemodynamically stable VT. In 14 patients, 16 VT morphologies induced by programmed right ventricular extrastimulation were reproducibly terminated by endocardial burst pacing (3 to 9 complexes). VT cycle lengths averaged 392 ± 97 ms (standard deviation) and ranged from 300 to 690 ms. The endocardial burst pacing cycle length used to terminate VT averaged 298 ± 93 ms (range 220 to 600 ms). External burst pacing terminated 14 of 16 VT morphologies (88%). The pacing cycle length used to terminate these 14 VTs averaged 282 ± 44 ms. The number of ventricular captures ranged from 5 to 20 beats. Failure to terminate 2 VT morphologies probably represented a failure of the device to capture the ventricle. Acceleration of VT occurred in 1 patient with burst external noninvasive pacing. These observations suggest that external burst pacing may be an effective means of terminating sustained VT in some patients.

(Am J Cardiol 1988;61:574–577)

Sustained ventricular tachycardia (VT) can be terminated by cardiac pacing from either an endocardial or epicardial site.[1-4] Overdrive endocardial burst ventricular pacing has been shown to terminate sustained VT in 60 to 90% of cases.[5,6] A few case reports have documented the use of external (transcutaneous) pacing in the termination of VT.[7-10] To determine the role that external pacing may play in the termination of VT, we compared the effectiveness of external to endocardial burst ventricular pacing for the termination of sustained VT.

Methods

There were 14 patients (3 women and 11 men), mean age 63 ± 9 years (mean ± standard deviation). Thirteen patients had coronary artery disease and 1 had dilated cardiomyopathy. All patients with coronary artery disease had had a myocardial infarction (>2 months before electrophysiologic testing). All were recruited from subjects undergoing routine electrophysiologic testing for sustained VT or ventricular fibrillation. Patients gave informed written consent before electrophysiologic testing. The protocol had been approved by the Clinical Investigation Committee of the University and Hospital.

Only patients with inducible sustained VT using programmed stimulation were candidates. Sustained VT had to be well tolerated and easily terminated on 2 occasions by burst ventricular pacing from an endocardial site to qualify for external pacing. To terminate ventricular tachycardia by both endocardial and external means, only burst ventricular pacing was used. The initial endocardial burst pacing cycle length was 50 to 70 ms less than that of the VT. Endocardial pacing was synchronized and performed at 2 times diastolic threshold for 3 to 10 beats initially. If VT persisted, then the pacing cycle length was reduced by 10- to 20-ms decrements.

For termination of VT by external pacing, we used a Zoll noninvasive temporary pacemaker (ZMI Corp.) modified to allow for tracking of a stimulus from a standard programmable stimulator. The upper rate limit of the standard unit (180 beats/minute) was increased by reducing the refractory period of the device. Asynchronous burst pacing could be performed in the VVT mode.

External burst ventricular pacing was performed after establishing the pacing threshold in sinus rhythm. The threshold for pacing during VT was ini-

tially set at 20 mA above the sinus pacing threshold. The initial pacing cycle length was set at or 20 ms above the endocardial cycle length that terminated the VT. If there was failure to capture consistently at this cycle length, then the output was increased in 20-mA increments until consistent capture was obtained. If VT persisted, the cycle length of pacing was shortened by 10- to 20-ms increments to facilitate ventricular capture and termination of VT (Figure 1). If external pacing was not successful in terminating the ventricular tachycardia, then endocardial pacing or direct current cardioversion was used.

Patients were sedated with midazolam, 4 to 8 mg intravenously in 2 mg divided doses every 5 minutes until somnolence. Both induction and termination of VT were performed with the patients sedated.

Results

In 14 patients, a total of 25 different VT morphologies were induced in the basal state. Only 2 VT morphologies were hemodynamically stable and easily terminated by endocardial burst pacing. All 14 patients then underwent drug testing with an antiarrhythmic agent or agents. Fourteen VT morphologies were induced and reproducibly terminated with endocardial pacing only after the administration of an antiarrhythmic agent. These agents failed to prevent induction of VT but did slow VT rates. These 16 VT morphologies were then tested for termination by external burst pacing (Table I).

For endocardial pacing, the stimulation threshold ranged from 0.3 to 1.0 mA at the right ventricular apex. The current used for endocardial induction and termination of VT was set at twice diastolic pacing threshold with the output set at a minimum of 1.0 mA (range 1.0 to 2.0) The pacing threshold for external pacing during sinus rhythm averaged 76 ± 14 mA. Increasing the current by merely 20 mA for external pacing during VT rarely allowed for consistent ventricular capture during burst pacing. Thus, pacing currents generally required to terminate VT averaged 107 ± 23 mA (range 60 to 140) and were significantly higher than those in sinus rhythm ($p < 0.005$).

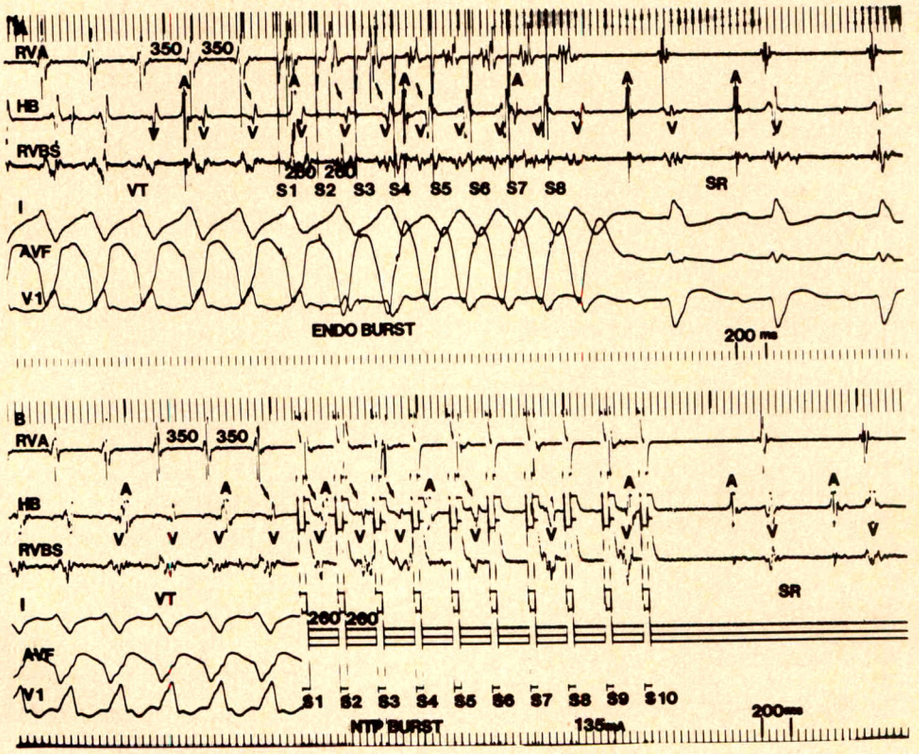

FIGURE 1. ***A*** **(patient no. 2) is an example of ventricular tachycardia (VT) termination by endocardial burst (Endo Burst) ventricular pacing. The intracardiac electrograms (RVA = right ventricular apex; HB = HIS bundle; RVBS = right ventricular basal septum) are recorded simultaneously with surface leads I, aVF, V_1. The VT morphology is one of right bundle branch block at a cycle length of 350 ms. Atrioventricular dissociation is present during both VT and pacing.** ***Arrows*** **indicate the sequence of activation. The apex of the right ventricle is activated before the basal septum (HB, RVBS) during VT. Termination of VT is achieved by burst pacing from the RVA for 8 beats (S1 through S8) at a cycle length of 260 ms. Sinus rhythm (SR) follows. A = atrium; V = ventricle; S = stimulus.** ***B*** **is an example of VT termination in the same patient by external noninvasive temporary pacing (NTP). Intracardiac and surface electrograms are the same as in** ***A*****. The VT morphology and rate are the same. Atrioventricular dissociation is present during both VT and external pacing. With external pacing, VT is terminated and sinus rhythm follows. External pacing at 135 mA allowed for intermittent ventricular capture. S1 fuses with the VT. S2 and S3 capture but S4 fails to capture. S5, S7 and S9 capture the ventricle. Only 6 of 10 stimuli capture the ventricle despite the high current. Activation of the ventricle during external pacing appears to start at the apex and move cephalad (*** ***arrows*** **indicate sequence of activation: RVA to HB, to RVBS electrograms). This suggests that only a small part of the ventricle is activated with external pacing.**

* Termination without antiarrhythmic agents; all other VTs studied while patients were taking antiarrhythmic agents.

a, b, = 2 different VT morphologies in the same patient; bpm = beats/min; CL = cycle length; Endo = endocardial; EXP = external pacing; EXP-mA = external pacing current strength; LAD = left axis deviation; LBBB = left bundle branch block; NL = normal axis; RAD = right axis deviation; VT = ventricular tachycardia.

The 16 VTs had an average cycle length of 392 ± 97 ms. The endocardial burst pacing cycle length used to terminate VT averaged 298 ± 93 ms. The lowest number of beats terminating VT is listed in Table I.

External burst pacing terminated 14 of 16 VT morphologies (Table I). The average cycle lengths of the 14 VTs was 372 ± 59 ms. The average external pacing cycle length that successfully terminated VT was 282 ± 44 ms. The fewest number of ventricular captures terminating VT is listed in Table I. The cycle lengths and number of beats used by both methods were similar (Table I).

External pacing failed to terminate 2 VTs. In patient 7, VT with a left bundle branch block configuration could not be terminated at current strengths of 120 mA. In this patient, conversion to a different VT morphology with acceleration in the rate occurred with external pacing (Figure 2). This VT terminated spontaneously after about 20 seconds. In the same patient, a VT with right bundle branch block morphology was easily terminated with external pacing at 135 mA. Patient 11 was receiving amiodarone and mexiletine, and his VT was slowed to a cycle length of 690 ms. Endocardial pacing easily terminated his VT with 3 stimuli at a cycle length of 600 ms that was synchronized to the VT beats. However, external burst pacing with current strengths between 60 and 100 mA and cycle lengths of 600 to 430 ms failed to terminate VT. Endocardial electrograms were not available and it was difficult to determine if there was ventricular capture by the external device.

Ventricular activation during external pacing was difficult to ascertain with the present recording apparatus. Intracardiac electrograms helped to determine the activation sequence. Only ventricular capture was seen despite the use of as much as 140 mA in 1 patient.

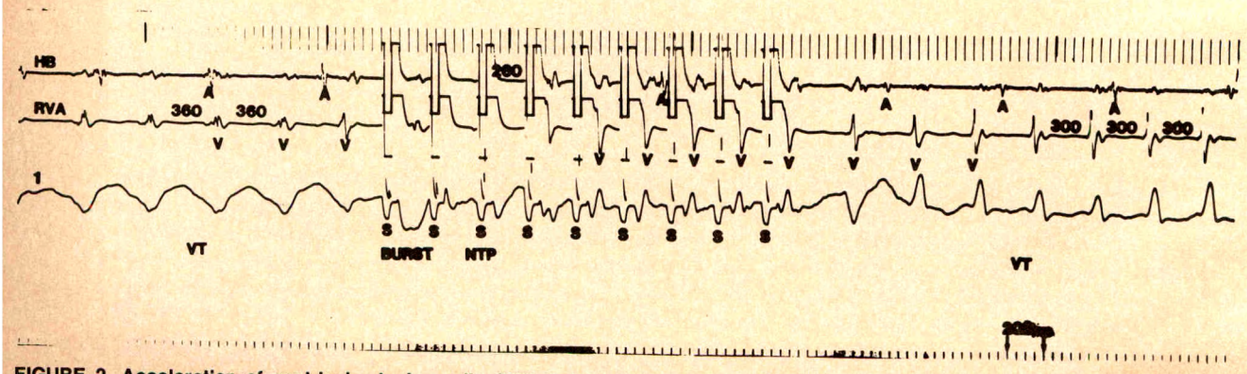

FIGURE 2. Acceleration of ventricular tachycardia (VT) by external noninvasive temporary pacing (NTP) in patient 7. Intracardiac electrograms are recorded simultaneously with lead I. Atrioventricular dissociation is present during both VT and pacing. The VT has a cycle length of 360 ms and is predominantly negative in lead I. Burst external pacing at 260 ms converts the first VT to a second faster VT (cycle length 300 ms). The first 3 stimuli (S) fail to capture the ventricle. Stimuli 4 through 9 consistently capture the ventricle but do not suppress the VT. Abbreviations as in Figure 1.

From some tracings, it appears that external pacing activates the ventricular apex and spreads cephalad (Figure 1).

In order to reduce the muscular discomfort of external pacing, all patients were given 4 to 8 mg of midazolam intravenously before induction and termination of VT with both methods. While in the sedated state, all patients tolerated external pacing well and following the study, no patient recalled the experience as particularly unpleasant. Midazolam produced Cheyne-Stokes respiration in 3 patients but no patient required ventilatory assistance.

Discussion

Termination of sustained VT by pacing techniques is well established.[1-6,11] Our experience with endocardial overdrive burst pacing for termination of VT is similar to that of others,[11] with VT rates >200 beats/min being difficult to terminate. In contrast, 90% of VTs with rates <200 beats/min are terminated by pacing.[5] External noninvasive pacing may also be useful in terminating sustained VT.[7-10] To evaluate the safety and effectiveness of external noninvasive pacing for the termination of sustained VT, we compared it with endocardial burst pacing. We chose endocardial burst pacing because it is an established modality with a success rate of approximately 90%.[5] In addition, it is the pacing technique most easily duplicated by the modified external pacemaker used in this study; our modified Zoll noninvasive temporary pacemaker can deliver a burst of asynchronous stimuli.

Our data show that external noninvasive burst ventricular pacing is quite comparable to endocardial right ventricular burst pacing for the termination of VT. Fourteen of 16 episodes (88%) of sustained, hemodynamically stable VT were terminated by external pacing. The rate of the VTs terminated by external pacing averaged 163 beats/min.

The inability of external noninvasive pacing to terminate some VTs may be due to either a tachycardia unresponsive to pacing or a failure of the device to actually capture the heart.[12,13] In both of our failures, adequate capture was not achieved, probably because higher pacing currents were required. In fact, we found that the external pacing thresholds required to terminate VT were significantly higher than those required to pace in sinus rhythm. It has been previously recognized that increasing the current (mA) for endocardial burst pacing to 10 to 14 mA facilitates capture and VT termination.[14] Our data suggest that high current strengths are equally important in termination of VT with external pacing.

Rapid ventricular pacing can result in acceleration of VT rate or induction of ventricular fibrillation.[6,11] The incidence of acceleration of the VT rate with endocardial burst pacing ranges from 4 to 24%.[5,6,11] Our incidence of acceleration of VT rate with external pace termination was 6% (1 of 16 VT morphologies). As expected, external burst ventricular pacing for VT termination carries much the same risk of acceleration as endocardial burst pacing.

This study has several limitations. It was not a general efficacy study for external pace termination of VT. Our patient population was preselected to allow comparison of 2 pacing modalities. VT rates were slower and allowed for endocardial burst pacing termination. External burst pacing was not used in termination of VTs that were rapid and had failed endocardial termination. The cycle lengths needed to terminate tachycardia were predetermined for external pacing by results of endocardial burst termination. During spontaneous VT, pacing parameters would need to be determined for external pacing. Determining ventricular capture at rapid burst rates is difficult with existing recording equipment because the external stimulus artifact obliterates conventional surface electrocardiographic tracings.

From these preliminary observations it seems reasonable to conclude that external burst ventricular pacing will be an effective means of terminating some forms of VT,. The relative simplicity, safety and reasonably good patient tolerance of the technique make it an attractive potential addition to current methods of antitachycardia pacing. We advise caution, however, because the general clinical utility and safety of external burst ventricular pacing as a primary therapy for VT has yet to be established. Further comparisons with more sophisticated modalities, such as synchronized programmed stimulation and ramp pacing, will be necessary to better define the exact role and limitation of this technique.

Prognostic Significance of Arrhythmia Inducibility or Noninducibility at Initial Electrophysiologic Study in Survivors of Cardiac Arrest

ROGER A. FREEDMAN, MD, CHARLES D. SWERDLOW, MD, VIVIAN SODERHOLM-DIFATTE, BA, and JAY W. MASON, MD

The value of arrhythmia inducibility or noninducibility at initial electrophysiologic study to predict the likelihood of arrhythmia recurrence was assessed in 150 consecutive survivors of cardiac arrest. Ventricular tachycardia (≥6 beats) or ventricular fibrillation was induced in 113 patients (75%); ventricular arrhythmia could not be induced in 37 patients (25%). During follow-up of a mean of 16 months (range 1 to 72), there were 65 arrhythmia recurrences, 34 of them fatal, in 58 patients. Multivariate regression analysis showed that inducibility at initial study of ventricular tachycardia or ventricular fibrillation was an independent predictor of total arrhythmia recurrence ($p < 0.0001$) and fatal arrhythmia recurrence ($p = 0.02$). At 1 year, 25 ± 5% of patients with an inducible arrhythmia had a fatal arrhythmia recurrence compared with only 4 ± 4% of patients without ($p = 0.003$). The nature of the inducible arrhythmia had no additional predictive value. Inducibility or noninducibility of ventricular arrhythmias at initial electrophysiologic study is a powerful, independent predictor of subsequent arrhythmia recurrence in survivors of cardiac arrest. Patients without inducible arrhythmias have a low frequency of fatal arrhythmia recurrence.

(Am J Cardiol 1988;61:578–582)

The incidence of recurrent cardiac arrest in patients who have been successfully hospitalized and discharged following a first episode of cardiac arrest is 10 to 25% in the first year and approximately 5% a year subsequently.[1,2] All medical and surgical antiarrhythmic therapy advocated in survivors of cardiac arrest have substantial morbidity and the potential for worsening arrhythmias.[3–5] Prospective identification of patients at greater or lower risk for recurrence could determine the need to institute such therapy.

Ventricular tachycardia (VT) or ventricular fibrillation (VF) can be induced during initial electrophysiologic study (when the patient is receiving no antiarrhythmic drug) in most survivors of cardiac arrest.[6–13] Some previous studies[6,7,11,12] have suggested that patients in whom no arrhythmias are inducible are at low risk for recurrent cardiac arrest, while others have suggested no risk advantage in this group.[9,10,13] Several of these prior studies included small numbers of patients and most did not use actuarial methods to analyze recurrence. We used actuarial methods to determine the prognosis in 37 survivors of cardiac arrest without inducible arrhythmias, and compared their prognosis with that of 113 concurrent survivors of cardiac arrest who had inducible arrhythmias.

Methods

Patients: The patients are 150 consecutive survivors of cardiac arrest who underwent a uniform stimulation protocol at initial (i.e., without antiarrhythmic drug) electrophysiologic study. A patient was considered to have survived a cardiac arrest if he or she had a witnessed, sudden loss of consciousness, was pulseless and apneic and required external direct current cardioversion. Patients whose arrest occurred within 7 days of an acute myocardial infarction or cardiac surgery were excluded. Of the patients with myocardial

infarction, 90% had cardiac arrest >30 days after onset of the infarct.

Electrophysiologic study: All patients underwent electrophysiologic study after antiarrhythmic drugs had been withheld for at least 5 drug half-lives. Our ventricular arrhythmia induction protocol has been described previously.[14] It included rapid atrial and ventricular pacing, and up to 3 right ventricular extrastimuli delivered during sinus and ventricular-paced rhythm at 4 basic drive cycle lengths (400 to 600 ms). Ventricular stimulation was initially performed at the right ventricular apex, but it was repeated at a second right ventricular site if an endpoint (discussed next) was not met during stimulation at the apex. Left ventricular stimulation and isoproterenol infusion were not used to induce arrhythmias in these patients. If the patient had had documented, spontaneous, sustained monomorphic VT, the endpoint of the study was induction of 2 sustained monomorphic VT or completion of the stimulation protocol. In those without documented, spontaneous, sustained monomorphic VT, the endpoint of the study was the induction of 2 sustained VT or VF or completion of the protocol.

Induced VT was considered sustained if its duration was at least 15 seconds, and nonsustained if its duration was between 6 beats and 15 seconds. Patients were considered to have no inducible arrhythmias if <6 repetitive beats were reproducibly induced during the stimulation protocol. All episodes of polymorphic VT were either nonsustained or degenerated into VF within 15 seconds; hence all induced arrhythmias could be classified as sustained monomorphic VT, nonsustained VT or VF.

Therapy: In patients with inducible arrhythmias, attempts were made to identify a drug effective in preventing arrhythmia induction, using previously described criteria.[14] If an acutely effective drug was identified and was well tolerated, the patient was discharged receiving it. In patients in whom no acutely effective drug could be identified and in patients without arrhythmias inducible at initial study, therapy was chosen on an individual basis.

Follow-up: Patients were followed for a mean of 16 months (range 1 to 72) after initial electrophysiologic study. Patients or referring physicians were contacted at least every 3 months during follow-up to determine patient status. Follow-up ended on the date of the patient's death or cardiac transplantation, when no information was available on the patient's status (1 patient), or at the end of the study.

During follow-up a witnessed death was classified as sudden if it occurred within 1 hour of onset of symptoms, and an unwitnessed death was classified as sudden unless there was evidence of preceding circulatory failure.[15] All other deaths were classified as nonsudden. A sustained arrhythmia recurrence was diagnosed if sustained VT or VF was documented electrocardiographically, if the patient had syncope without other obvious cause or, in patients with implanted automatic defibrillators, if there was a shock not caused by sinus or supraventricular tachycardia or by malfunction of the device.

TABLE I Comparison of 37 Patients Without Inducible Arrhythmias With 113 Concurrent Patients With Inducible Arrhythmias

	Without Induced Arrhythmias	With Induced Arrhythmias	p Value
Age (yrs)	53 ± 17	56 ± 14	0.3
Male gender (%)	13 (35)	98 (87)	<0.0001
Structural heart disease			
Coronary artery disease* (%)	14 (38)	87 (77)	
Prior MI (%)	7 (19)	85 (75)	
LV aneurysm (%)	4 (11)	53 (47)	
Idiopathic cardiomyopathy (%)	16 (43)	20 (18)	0.0001
Valvular disease (%)	0 (0)	1 (1)	
None (%)	7 (19)	5 (4)	
LV ejection fraction†	45 ± 18	35 ± 14	0.02

* History of myocardial infarction or angina pectoris, or ≥70% stenosis of a coronary artery.

† Determined in 113 patients by either radionuclide or contrast ventriculography.

LV = left ventricular; MI = myocardial infarction.

Statistics: Continuous data are presented as mean ± 1 standard deviation. Student's *t* test statistic or the chi-square statistic was used to compare groups of patients. Actuarial survival estimates were by Kaplan-Meier method, and are expressed as probability ± standard error and compared using the Wilcoxon statistic.[16] Patients were censored at the time of nonsudden death or last follow-up. Multivariate regression analysis used stepwise Cox proportional-hazard model and the improvement chi-square statistic.[17]

Results

Electrophysiologic study: Sustained, monomorphic VT was induced in 82 patients (55%), VF in 23 (15%), nonsustained VT in 8 (5%) and no arrhythmia in 37 (25%). Clinical characteristics of the 37 patients without inducible arrhythmia are compared with those of the 113 patients with inducible arrhythmia in Table I.

Therapy: Therapy at discharge in the 37 patients without inducible arrhythmias was an antiarrhythmic drug in 19 (51%), automatic defibrillator in 7 (19%) and coronary artery bypass surgery in 3 (8%). There was no therapy in 8 (22%).

Of the 113 patients with inducible arrhythmias, 10 died and 2 underwent cardiac transplantation before hospital discharge. Therapy at discharge in the remaining 101 patients was an antiarrhythmic drug in 49 (49%), automatic defibrillator in 33 (33%), surgical myocardial ablation in 12 (12%), coronary artery bypass surgery in 4 (4%) and 3 patients (3%) did not receive therapy. Of the 49 patients with inducible arrhythmias who were discharged receiving an antiarrhythmic drug, the drug was found effective by serial electrophysiologic study in 13, ineffective in 11 and not tested in 25.

Arrhythmia recurrences: The actuarial incidences of fatal recurrence (sudden death) at 1 and 2 years were 20 ± 4% and 27 ± 5%, respectively. The actuarial

TABLE II Raw Arrhythmia Recurrence Data in Patients With and Without Inducible Arrhythmias During Mean Follow-Up of 16 Months

	Sudden Death	Nonfatal Arrhythmia	No Arrhythmia Recurrence
Inducible arrhythmia (n = 113)	32 (28%)	28* (25%)	60 (53%)
No inducible arrhythmia (n = 37)	2 (5%)	3 (8%)	32 (87%)

* Includes 7 patients who died suddenly during subsequent follow-up.

incidences of total recurrence (sudden death or sustained arrhythmia) at 1 and 2 years were 34 ± 4% and 41 ± 5%, respectively.

Arrhythmia recurrences for patients with and without arrhythmias induced at initial electrophysiologic study are listed in Table II. Recurrences were much less frequent in patients without inducible arrhythmias than in those with inducible arrhythmias. This difference is confirmed using actuarial methods (Figure 1). At 1 year, the risks of fatal and total arrhythmia recurrences were 6.3- and 2.9-fold greater, respectively, in patients with inducible arrhythmias than in those without.

Compared with patients without inducible arrhythmias, the increased relative risk of arrhythmia recurrence in patients with inducible arrhythmias was present regardless of the type of ventricular arrhythmia induced. Recurrence rates did not differ significantly between those whose induced arrhythmia was sustained monomorphic VT, VF or nonsustained VT.

Other univariate correlates of arrhythmia recurrence were New York Heart Association functional class, presence of coronary artery disease, age and ejection fraction.

By stepwise Cox multivariate regression survival analysis, arrhythmia inducibility at initial electrophysiologic study was an independent predictor of both total ($p < 0.0001$) and fatal ($p = 0.02$) arrhythmia recurrences. Other independent predictors were history of prior myocardial infarction and New York Heart Association functional class. Variables without significant independent predictive value for either fatal or total recurrences were age, gender, coronary artery disease and left ventricular aneurysm. Left ventricular ejection fraction was excluded from these analyses because it was not determined in all patients.

The wide variety of therapies used in these patients, and the fact that therapy was not prescribed in a controlled fashion, hinder analysis of the overall effect of therapy on arrhythmia recurrence. However, several observations are of interest. As expected, among patients with inducible arrhythmias at initial study, those receiving antiarrhythmic drugs predicted effective at follow-up study had fewer recurrences (1 year fatal recurrence rate is 25%) than those receiving drugs predicted ineffective (1 year fatal recurrence rate is 55%). However, patients without inducible arrhythmias at initial electrophysiologic study had even fewer recurrences (1 year fatal recurrence rate is 4%) than those with inducible arrhythmias receiving drugs predicted effective. In particular, the 12 patients without inducible arrhythmias (including 4 who received an implanted defibrillator) who were discharged receiving no antiarrhythmic drugs had no arrhythmia recurrences, fatal or nonfatal, through 1 year.

Discussion

Relations of arrhythmia inducibility to prognosis: The principal finding of this study is that arrhythmia inducibility at initial electrophysiologic study is a powerful, independent predictor of outcome in patients resuscitated from cardiac arrest. Several previous studies have assessed the correlation between arrhythmia inducibility and subsequent sudden death or arrhythmia recurrence in survivors of cardiac arrest. Ruskin et al[11] found no deaths in 14 survivors of cardiac arrest who did not have inducible VT or VF and were followed for 15 months. Morady et al[7] found no recurrences in 11 such patients followed for 19 months. However, other investigators have found high recurrence rates in survivors of cardiac arrest without inducible VT or VF. Roy et al[9] reported 10 sudden

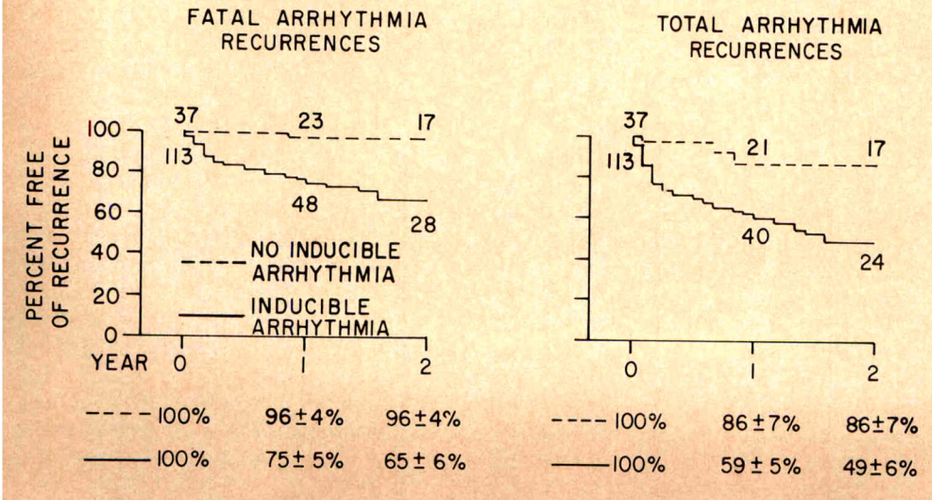

FIGURE 1. Actuarial curves for fatal (*left*) and total (*right*) arrhythmia recurrence stratified by presence or absence of inducible arrhythmias at initial electrophysiologic study. The numbers next to the curves indicate number of patients at risk. The numbers below the graphs indicate probability of freedom from recurrence ± standard error. The differences between curves for fatal arrhythmia recurrence are significant ($p = 0.003$). The differences between curves for total arrhythmia recurrence are significant ($p = 0.0006$).

deaths in 36 patients followed for 20 months, Henthorn et al[10] reported 7 sudden deaths and 6 nonfatal VT recurrences in 23 patients followed for 15 months and Eldar et al[13] reported 3 sudden deaths and 5 nonfatal recurrences in 33 patients followed for 27 months.

These previous studies have certain limitations. First, only 1 of them[13] used actuarial methods to assess the predictive value of initial arrhythmia inducibility. Second, a concurrent comparison group of survivors of cardiac arrest with inducible VT or VF was not always included.[10] Third, among those that found arrhythmia inducibility to be a significant prognostic factor, none used multivariate analysis to determine if its effect was independent of the effects of other variables.

In the present study, using actuarial analysis, we found that presence or absence of inducible VT or VF at initial electrophysiologic study was a strong univariate predictor of both fatal ($p = 0.003$) and total ($p = 0.0006$) arrhythmia recurrence. Further, the predictive value of the initial electrophysiologic study was independent of other predictors of arrhythmia recurrence. These findings contrast with those recently reported by Eldar et al,[13] who also used actuarial analysis but found no difference in prognosis between patients with and without arrhythmias inducible at initial electrophysiologic study. One possible explanation for the disparity is the much higher incidence of recurrent arrhythmias in the present study compared with that of Eldar et al.[13] For instance, in patients with inducible arrhythmias, the 1 year incidence of fatal arrhythmia recurrence was 8.5% in Eldar et al[13] versus 25% in the present study. The lower incidence of arrhythmia recurrences in the prior study may have limited its power in discerning a difference in prognosis between patients with and without inducible arrhythmias. Further, the disparity in recurrence rates suggests a difference in patient population.

Arrhythmia inducibility has been shown to be a predictor of prognosis in other patient populations. Denniss et al[18] have shown that after myocardial infarction, patients with inducible VT had a greater incidence of ventricular tachyarrhythmias and death than patients without inducible arrhythmias. In patients with spontaneous nonsustained VT, Gomes,[19] Buxton[20] and their co-workers have shown that patients with inducible arrhythmias were more likely to suffer sustained VT or sudden death. Thus, the prognostic implication of arrhythmia inducibility in our population of cardiac arrest survivors is paralleled by similar findings in other patient groups.

Significance of inducing nonsustained ventricular tachycardia or ventricular fibrillation: Some investigators[21,22] have questioned the significance of inducing nonsustained VT or VF, because these arrhythmias may be induced in some patients without spontaneous arrhythmias. In the present study, patients with nonsustained VT or VF induced at initial electrophysiologic study had significantly higher arrhythmia recurrence rates than patients with no inducible arrhythmia. These results suggest that in survivors of cardiac arrest, inducibility of nonsustained VT or VF may not be a nonspecific response.

Limitations: A weakness of this study is that therapy was not prescribed in a controlled fashion, and a wide range of therapy was used in both patients with and without inducible arrhythmias. Specifically, the influence of therapy on the natural history of our patients without inducible arrhythmias is not known. It is noteworthy that, among the patients without inducible arrhythmias, those who received no drug therapy had fewer recurrences than those who did receive antiarrhythmic drugs. This comparison is limited by the fact that therapy was not assigned in a controlled or randomized fashion.

A second limitation of this study is that ambulatory electrocardiographic monitoring was not routinely performed in the study population. Prior studies have yielded conflicting results on whether the frequency and complexity of ventricular premature beats are predictive of recurrent cardiac arrest.[23–25]

Implications: Why is arrhythmia inducibility at initial electrophysiologic study an independent predictor of arrhythmia recurrence in survivors of cardiac arrest? One possible explanation is that transient but not frequently recurrent metabolic disturbances, such as electrolyte abnormalities or ischemia, play a larger role in patients without inducible arrhythmias than in those with inducible arrhythmias. This hypothesis was not examined in the present study.

Ideally, only those survivors of sudden death at high risk for arrhythmia recurrence should receive potentially toxic antiarrhythmic drugs or major surgical procedures. In this study, arrhythmia inducibility at initial electrophysiologic study was a powerful predictor of arrhythmia recurrence. Patients with inducible arrhythmias had a 25% probability of fatal recurrence at 1 year, and aggressive therapy is indicated in this group. On the other hand, patients without inducible arrhythmias had only a 4% probability of fatal recurrence at 2 years, and the appropriateness of aggressive therapy in this group is therefore questionable.

Clinical Doppler Echocardiography

by José Missri, MD
0-914316-51-6 256 pp., April 1986, 175 illustrations, $55.00

The development and refinement of Doppler echocardiography represent a major advance in the diagnostic applications of ultrasound in heart disease.

Dr. Missri has written *Clinical Doppler Echocardiography* to provide clinical cardiologists, postdoctoral fellows and "echo" technologists with practical information on cardiac Doppler applied to acquired and congenital disease.

Clearly written, logically presented, generously illustrated—including 4-color examples of Doppler color-flow mapping—and thoroughly indexed, *Clinical Doppler Echocardiography* is a must addition for personal and medical center libraries.

Table of Contents (in brief)

INTRODUCTION TO DOPPLER ECHOCARDIOGRAPHY
PRINCIPLES OF DOPPLER ECHOCARDIOGRAPHY AND INSTRUMENTATION
DOPPLER EXAMINATION OF THE HEART AND GREAT VESSELS
DOPPLER EVALUATION OF MITRAL VALVE DISEASE
DOPPLER EVALUATION OF AORTIC VALVE DISEASE
DOPPLER EVALUATION OF RIGHT SIDED LESIONS AND PULMONARY HYPERTENSION
DOPPLER ASSESSMENT OF PROSTHETIC VALVES

Transderm-Nitro® nitroglycerin
Transdermal Therapeutic System

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

INDICATIONS AND USAGE
This drug product has been conditionally approved by the FDA for the prevention and treatment of angina pectoris due to coronary artery disease. The conditional approval reflects a determination that the drug may be marketed while further investigation of its effectiveness is undertaken. A final evaluation of the effectiveness of the product will be announced by the FDA.

CONTRAINDICATIONS
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.
In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.
Transdermal nitroglycerin systems should be removed before attempting defibrillation or cardioversion because of the potential for altered electrical conductivity which may enhance the possibility of arcing, a phenomenon associated with the use of defibrillators.

PRECAUTIONS
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.
Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.
Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea and vomiting. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued. In some patients, dermatitis may occur.

DOSAGE AND ADMINISTRATION
Therapy should be initiated with application of one Transderm-Nitro 5 mg/24 hr system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area.
Transderm-Nitro system should not be applied to the distal parts of the extremities.
The usual dosage is one Transderm-Nitro 5 mg/24 hr system. Some patients, however, may require the Transderm-Nitro 10 mg/24 hr system. If a single Transderm-Nitro 5 mg/24 hr system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 mg/24 hr systems or one Transderm-Nitro 10 mg/24 hr system. More systems may be added as indicated by continued careful monitoring of clinical response. The Transderm-Nitro 2.5 mg/24 hr system is useful principally for decreasing the dosage gradually, though it may provide adequate therapy for some patients when used alone. The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension especially during orthostasis indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.
Do not store above 86°F (30°C).

PATIENT INSTRUCTIONS FOR APPLICATIONS
A patient leaflet is supplied with the systems.

FOR MANY HYPERTENSIVE PATIENTS

Start with Once-a-Day

VASOTEC®

(ENALAPRIL MALEATE | MSD)

Certain CNS effects, such as impairment of memory, nightmares, or depression, have not been characteristic of VASOTEC.

Little or No Interference with Physical or Mental Activity

Certain subjective symptoms such as malaise and drowsiness, which may interfere with physical or mental activity, have not been characteristic of VASOTEC—a fact that may be related to the specificity of action of VASOTEC on the renin-angiotensin-aldosterone system.

VASOTEC is contraindicated in patients who are hypersensitive to this product.

Angioedema of the face, extremities, lips, tongue, glottis, and/or larynx has been reported in patients treated with angiotensin-converting-enzyme (ACE) inhibitors, including VASOTEC (0.2% of patients treated with VASOTEC in clinical trials). In such cases, VASOTEC should be promptly discontinued and the patient carefully observed until the swelling disappears. Angioedema associated with laryngeal edema may be fatal. **Where there is involvement of the tongue, glottis, or larynx, likely to cause airway obstruction, appropriate therapy, e.g., subcutaneous epinephrine solution 1:1000 (0.3 mL to 0.5 mL), should be promptly administered.**

Excessive hypotension was rarely seen in uncomplicated hypertensive patients but is a possible consequence of enalapril use in severely salt/volume-depleted persons, such as those treated vigorously with diuretics or patients on dialysis. In using VASOTEC, consideration should be given to the fact that another ACE inhibitor, captopril, has caused agranulocytosis, particularly in patients with renal impairment or collagen vascular disease, and the available data are insufficient to show that VASOTEC does not have a similar risk.

It May Change the Way Your Patients Feel on Antihypertensive Therapy

VASOTEC®

(ENALAPRIL MALEATE | MSD)

Contraindications: VASOTEC® (Enalapril Maleate, MSD) is contraindicated in patients who are hypersensitive to this product.

Warnings: *Angioedema:* Angioedema of the face, extremities, lips, tongue, glottis, and/or larynx has been reported in patients treated with ACE inhibitors, including VASOTEC. In such cases, VASOTEC should be promptly discontinued and the patient carefully observed until the swelling disappears. In instances where swelling has been confined to the face and lips, the condition has generally resolved without treatment, although antihistamines have been useful in relieving symptoms. Angioedema associated with laryngeal edema may be fatal. **Where there is involvement of the tongue, glottis, or larynx, likely to cause airway obstruction, appropriate therapy, e.g., subcutaneous epinephrine solution 1:1000 (0.3 mL to 0.5 mL), should be promptly administered.** (See ADVERSE REACTIONS.)

Hypotension: Excessive hypotension was rarely seen in uncomplicated hypertensive patients but is a possible consequence of enalapril use in severely salt/volume-depleted persons such as those treated vigorously with diuretics or patients on dialysis. (See PRECAUTIONS, *Drug Interactions* and ADVERSE REACTIONS.) In patients with severe congestive heart failure, with or without associated renal insufficiency, excessive hypotension has been observed and may be associated with oliguria and/or progressive azotemia, and rarely with acute renal failure and/or death. Because of the potential fall in blood pressure in these patients, therapy should be started under very close medical supervision. Such patients should be followed closely for the first two weeks of treatment and whenever the dose of enalapril and/or diuretic is increased.

If hypotension occurs, the patient should be placed in supine position and, if necessary, receive an intravenous infusion of normal saline. A transient hypotensive response is not a contraindication to further doses, which usually can be given without difficulty once the blood pressure has increased after volume expansion.

Neutropenia/Agranulocytosis: Another ACE inhibitor has been shown to cause agranulocytosis and bone marrow depression, rarely in uncomplicated patients but more frequently in patients with renal impairment, especially if they also have a collagen vascular disease. Available data from clinical trials of enalapril are insufficient to show that enalapril does not cause agranulocytosis at similar rates. Foreign marketing experience has revealed several cases of neutropenia or agranulocytosis in which a causal relationship to enalapril cannot be excluded. Periodic monitoring of white blood cell counts in patients with collagen vascular disease and renal disease should be considered.

Precautions: *General: Impaired Renal Function:* As a consequence of inhibiting the renin-angiotensin-aldosterone system, changes in renal function may be anticipated in susceptible individuals. In patients with severe congestive heart failure whose renal function may depend on the activity of the renin-angiotensin-aldosterone system, treatment with ACE inhibitors, including VASOTEC, may be associated with oliguria and/or progressive azotemia and rarely with acute renal failure and/or death.

In clinical studies in hypertensive patients with unilateral or bilateral renal artery stenosis, increases in blood urea nitrogen and serum creatinine were observed in 20% of patients. These increases were almost always reversible upon discontinuation of enalapril and/or diuretic therapy. In such patients, renal function should be monitored during the first few weeks of therapy.

Some hypertensive patients with no apparent preexisting renal vascular disease have developed increases in blood urea and serum creatinine, usually minor and transient, especially when VASOTEC has been given concomitantly with a diuretic. This is more likely to occur in patients with preexisting renal impairment. Dosage reduction of VASOTEC and/or discontinuation of the diuretic may be required.

Evaluation of the hypertensive patient should always include assessment of renal function. (See DOSAGE AND ADMINISTRATION in complete Prescribing Information.)

Hyperkalemia: Elevated serum potassium (greater than 5.7 mEq/L) was observed in approximately 1% of hypertensive patients in clinical trials. In most cases these were isolated values which resolved despite continued therapy. Hyperkalemia was a cause of discontinuation of therapy in 0.28% of hypertensive patients. Risk factors for the development of hyperkalemia may include renal insufficiency, diabetes mellitus, and the concomitant use of agents to treat hypokalemia. (See *Drug Interactions*.)

Surgery/Anesthesia: In patients undergoing major surgery or during anesthesia with agents that produce hypotension, enalapril may block angiotensin II formation secondary to compensatory renin release. If hypotension occurs and is considered to be due to this mechanism, it can be corrected by volume expansion.

Information for Patients:

Angioedema: Angioedema, including laryngeal edema, may occur especially following the first dose of enalapril. Patients should be so advised and told to report immediately any signs or symptoms suggesting angioedema (swelling of face, extremities, eyes, lips, tongue, difficulty in breathing) and to take no more drug until they have consulted with the prescribing physician.

Hypotension: Patients should be cautioned to report lightheadedness especially during the first few days of therapy. If actual syncope occurs, the patients should be told to discontinue the drug until they have consulted with the prescribing physician.

All patients should be cautioned that excessive perspiration and dehydration may lead to an excessive fall in blood pressure because of reduction in fluid volume. Other causes of volume depletion such as vomiting or diarrhea may also lead to a fall in blood pressure; patients should be advised to consult with the physician.

Hyperkalemia: Patients should be told not to use salt substitutes containing potassium without consulting their physician.

Neutropenia: Patients should be told to report promptly any indication of infection (e.g., sore throat, fever) which may be a sign of neutropenia.

NOTE: As with many other drugs, certain advice to patients being treated with enalapril is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects.

Drug Interactions:

Hypotension: Patients on Diuretic Therapy: Patients on diuretics and especially those in whom diuretic therapy was recently instituted may occasionally experience an excessive reduction of blood pressure after initiation of therapy with enalapril. The possibility of hypotensive effects with enalapril can be minimized by either discontinuing the diuretic or increasing the salt intake prior to initiation of treatment with enalapril. If it is necessary to continue the diuretic, provide medical supervision for at least one hour after the initial dose. (See WARNINGS and DOSAGE AND ADMINISTRATION in complete Prescribing Information.)

Agents Causing Renin Release: The antihypertensive effect of VASOTEC is augmented by antihypertensive agents that cause renin release (e.g., diuretics).

Other Cardiovascular Agents: VASOTEC® (Enalapril Maleate, MSD) has been used concomitantly with beta-adrenergic-blocking agents, methyldopa, nitrates, calcium-blocking agents, hydralazine, and prazosin without evidence of clinically significant adverse interactions.

Agents Increasing Serum Potassium: VASOTEC may attenuate potassium loss caused by thiazide-type diuretics. Potassium-sparing diuretics (e.g., spironolactone, triamterene, or amiloride), potassium supplements, or potassium-containing salt substitutes may lead to significant increases in serum potassium. Therefore, if concomitant use of these agents is indicated, they should be used with caution and with frequent monitoring of serum potassium.

Pregnancy--Category C: There was no fetotoxicity or teratogenicity in rats treated with up to 200 mg/kg/day of enalapril (333 times the maximum human dose). Fetotoxicity, expressed as a decrease in average fetal weight, occurred in rats given 1200 mg/kg/day of enalapril but did not occur when these animals were supplemented with saline. Enalapril was not teratogenic in rabbits. However, maternal and fetal toxicity occurred in some rabbits at doses of 1 mg/kg/day or more. Saline supplementation prevented the maternal and fetal toxicity seen at doses of 3 and 10 mg/kg/day, but not at 30 mg/kg/day (50 times the maximum human dose).

There are no adequate and well-controlled studies in pregnant women. VASOTEC should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is secreted in human milk. Because many drugs are secreted in human milk, caution should be exercised when VASOTEC is given to a nursing mother.

Pediatric Use: Safety and effectiveness in children have not been established.

Adverse Reactions: VASOTEC has been evaluated for safety in more than 10,000 patients, including over 1000 patients treated for one year or more. VASOTEC has been found to be generally well tolerated in controlled clinical trials involving 2677 patients.

The most frequent clinical adverse experiences in controlled trials were: headache (4.8%), dizziness (4.6%), and fatigue (2.8%). For the most part, adverse experiences were mild and transient in nature. Discontinuation of therapy was required in 6.0% of patients. In clinical trials, the overall frequency of adverse experiences was not related to total daily dosage within the range of 10 to 40 mg. The overall percentage of patients treated with VASOTEC reporting adverse experiences was comparable to placebo.

Other adverse experiences occurring in greater than 1% of patients treated with VASOTEC in controlled clinical trials were: diarrhea (1.6%), rash (1.5%), hypotension (1.4%), cough (1.3%), nausea (1.3%), and orthostatic effects (1.3%).

Clinical adverse experiences occurring in 0.5% to 1.0% of patients in the controlled trials or since the drug was marketed include:

Cardiovascular: Syncope, orthostatic hypotension, palpitations, chest pain.

Nervous System: Insomnia, nervousness, paresthesia, somnolence.

Gastrointestinal System: Abdominal pain, vomiting, dyspepsia.

Renal: Renal dysfunction, renal failure, oliguria. (See PRECAUTIONS and DOSAGE AND ADMINISTRATION in complete Prescribing Information.)

Other: Dyspnea, muscle cramps, hyperhidrosis, impotence, pruritus, asthenia.

Angioedema: Angioedema has been reported in patients receiving VASOTEC (0.2%). Angioedema associated with laryngeal edema may be fatal. If angioedema of the face, extremities, lips, tongue, glottis, and/or larynx occurs, treatment with VASOTEC should be discontinued and appropriate therapy instituted immediately. (See WARNINGS.)

Hypotension: Combining the results of clinical trials in patients with hypertension or congestive heart failure, hypotension (including postural hypotension and other orthostatic effects) was reported in 2.3% of patients following the initial dose of enalapril or during extended therapy. In the hypertensive patients, hypotension occurred in 0.9% and syncope occurred in 0.5% of patients. Hypotension or syncope was a cause for discontinuation of therapy in 0.1% of hypertensive patients. (See WARNINGS.)

Clinical Laboratory Test Findings:

Hyperkalemia: (See PRECAUTIONS.)

Creatinine, Blood Urea Nitrogen: In controlled clinical trials, minor increases in blood urea nitrogen and serum creatinine, reversible upon discontinuation of therapy, were observed in about 0.2% of patients with essential hypertension treated with VASOTEC alone. Increases are more likely to occur in patients receiving concomitant diuretics or in patients with renal artery stenosis. (See PRECAUTIONS.)

Hemoglobin and Hematocrit: Small decreases in hemoglobin and hematocrit (mean decreases of approximately 0.3 g% and 1.0 vol%, respectively) occur frequently in hypertensive patients treated with VASOTEC but are rarely of clinical importance unless another cause of anemia coexists. In clinical trials, less than 0.1% of patients discontinued therapy due to anemia.

Other (Causal Relationship Unknown): Rarely, elevations of liver enzymes and/or serum bilirubin have occurred.

In marketing experience, rare cases of neutropenia, thrombocytopenia, and bone marrow depression have been reported.

Dosage and Administration: In patients who are currently being treated with a diuretic, symptomatic hypotension occasionally may occur following the initial dose of VASOTEC. The diuretic should, if possible, be discontinued for two to three days before beginning therapy with VASOTEC to reduce the likelihood of hypotension. (See WARNINGS.) If the patient's blood pressure is not controlled with VASOTEC alone, diuretic therapy may be resumed.

If the diuretic cannot be discontinued, an initial dose of 2.5 mg (break the 5-mg tablet) should be used under medical supervision for at least one hour to determine whether excess hypotension will occur. (See WARNINGS and PRECAUTIONS, *Drug Interactions.)*

The recommended initial dose in patients not on diuretics is 5 mg once a day. Dosage should be adjusted according to blood pressure response. The usual dosage range is 10 to 40 mg per day administered in a single dose or in two divided doses. In some patients treated once daily, the antihypertensive effect may diminish toward the end of the dosing interval. In such patients, an increase in dosage or twice-daily administration should be considered. If blood pressure is not controlled with VASOTEC alone, a diuretic may be added.

Concomitant administration of VASOTEC with potassium supplements, potassium salt substitutes, or potassium-sparing diuretics may lead to increases of serum potassium (see PRECAUTIONS).

Dosage Adjustment in Renal Impairment: The usual dose of enalapril is recommended for patients with a creatinine clearance >30 mL/min (serum creatinine of up to approximately 3 mg/dL). For patients with creatinine clearance ≤30 mL/min (serum creatinine ≥3 mg/dL), the first dose is 2.5 mg once daily. The dosage may be titrated upward until blood pressure is controlled or to a maximum of 40 mg daily. For dialysis patients, the initial dose and the dose on dialysis days is 2.5 mg/day. Dosage on nondialysis days should be adjusted depending on blood pressure response.

Dual Balloon Technique for Valvuloplasty of Aortic Stenosis in Adults

JEFFREY M. ISNER, MD, DEEB N. SALEM, MD, MARK R. DESNOYERS, MD, CONSTANCE D. FIELDS, MD, KIMBERLY R. HALABURKA, BS, GERALYN A. SLOVENKAI, BS, THOMAS J. HOUGEN, MD, ERIC J. EICHHORN, MD, and KENNETH ROSENFIELD, MD

A dual balloon technique was studied in 16 patients with aortic stenosis in whom results with a single balloon (up to 20 mm, 5.5 cm or 25 mm, 3.0 cm in diameter and length, respectively) were judged to be suboptimal. Dual balloon valvulopasty was performed using 2 balloons advanced and inflated simultaneously across the stenotic aortic valve orifice. For the group as a whole, the average peak transvalvular gradient was reduced from 79 ± 8 to 57 ± 7 mm Hg (mean ± standard error) using a single balloon ($p < 0.0005$), and reduced further to 36 ± 4 mm Hg using dual balloons ($p < 0.0005$ compared with single balloon results). Similarly, calculated aortic valve orifice area was increased from 0.45 ± 0.04 to 0.57 ± 0.05 cm^2 using a single balloon ($p < 0.0005$), and further increased to 0.77 ± 0.06 cm^2 using dual balloons ($p < 0.0005$). Dual balloon dilation caused no complications directly attributable to the use of 2 balloons, including no exacerbation of aortic regurgitation. These results suggest that dual balloon valvuloplasty is safe and efficacious in selected patients with aortic stenosis.

(Am J Cardiol 1988;61:583–589)

Pioneering work by Cribier et al[1,2] in France and McKay et al[3] in the U.S. established the fact that balloon valvuloplasty could accomplish hemodynamic and clinical palliation in most elderly patients with aortic stenosis (AS). Findings reported in these early and other subsequent[4,5] investigations, however, have indicated that when balloon valvuloplasty is performed using 1 or a series of single balloon catheters, the improvement in calculated aortic valve area achieved after valvuloplasty is often modest. Further, preliminary follow-up data recorded noninvasively using Doppler echocardiography or invasively during repeat cardiac catheterization suggests that restenosis may develop in ≥20% of patients followed for ≥6 months after a successful valvuloplasty.[6–8] Accordingly, a number of modifications in the instrumentation and technique used for aortic balloon valvuloplasty have been proposed to augment both the magnitude and duration of acute hemodynamic improvement.[9] We describe results of 1 such technical modification, simultaneous inflation of 2 balloons in 16 patients in whom results obtained using a single balloon were judged to be suboptimal.

From the Departments of Medicine (Cardiology), Pathology and Pediatrics (Cardiology), New England Medical Center/Tufts University School of Medicine, Boston, Massachusetts. This study was supported in part by grant HL 32747-01 and contract NO1-HC55010 from the National Heart, Lung, and Blood Institute, Bethesda, Maryland, and the Eleanor Naylor Dana Charitable Trust, New York, New York. Drs. Fields and Eichhorn were Research Fellows of the American Heart Association's Massachusetts Affiliate during this study. Manuscript received September 3, 1987; revised manuscript received and accepted October 28, 1987.

Dr. Eichhorn's present address: Department of Medicine (Cardiology), Veteran's Administration Hospital, Dallas, Texas.

Address for reprints: Jeffrey M. Isner, MD, Box 70, New England Medical Center, 171 Harrison Avenue, Boston, Massachusetts 02111.

Methods

Patients: The patients selected for dual balloon valvuloplasty constitute a subset of 16 patients (30%) from a total of 51 patients in whom aortic balloon valvuloplasty was performed at our institution during the past

15 months. Patients were judged to be candidates for balloon valvuloplasty in general if a previous cardiac catheterization (or in some cases Doppler echocardiographic examination) documented critical AS and no more than 2+/4+ aortic regurgitation; the patient, because of age or accompanying medical disorders, was considered either noneligible or high risk for aortic valve replacement; or the patient was an operative candidate but refused to undergo surgery. Among 51 such patients, 16 were selected for dual balloon valvuloplasty because the results obtained using 1 or a series of single balloons were judged to be suboptimal; suboptimal was defined as a calculated aortic valve area <0.50 cm^2, a residual transvalvular gradient >35 mm Hg or both. In addition, several patients who fulfilled these criteria were further excluded from consideration for dual balloon valvuloplasty when it was judged that certain technical factors (e.g., severe peripheral vascular disease, small body habitus) might make the dual balloon technique excessively hazardous. Each patient gave informed consent in accordance with a protocol approved by the Institutional Human Investigations Review Committee.

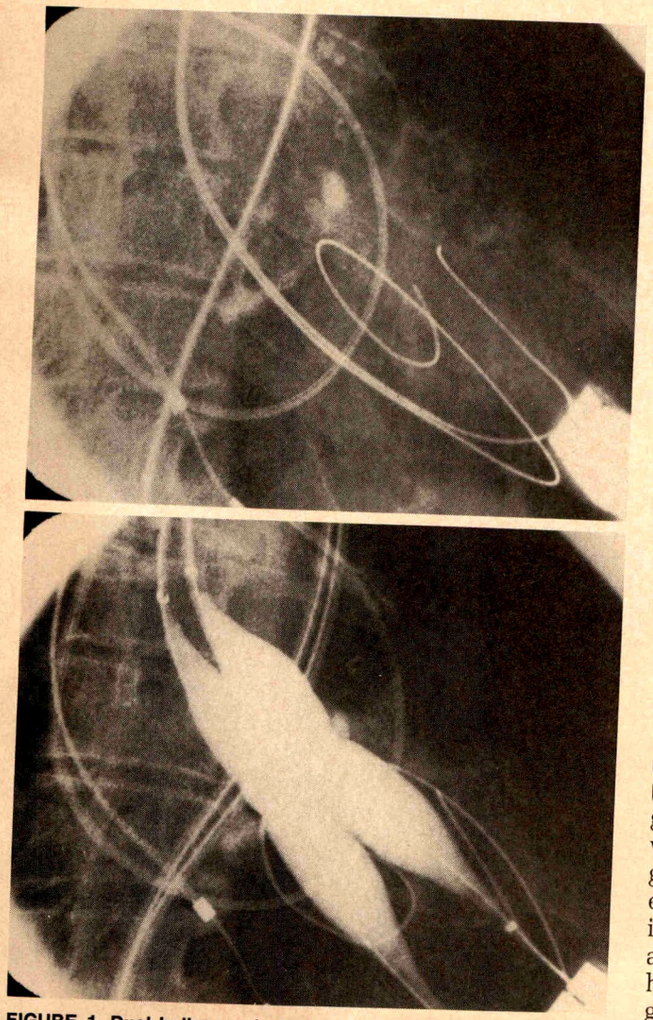

FIGURE 1. Dual balloon valvuloplasty in patient 6 (Table I). *Top*, exchange wires in place across aortic valve. *Bottom*, at full inflation of two 18 mm, 5.5 cm balloons, a "waist" persists at the (heavily calcified) valvular level.

Technique of single balloon valvuloplasty: All patients first underwent balloon valvuloplasty performed with 1 or a series of single balloons as described previously.[4] Briefly, under local lidocaine anesthesia, a small cutdown was performed to expose the right or left common femoral, superficial femoral and profunda femoris arteries. The introducer sheath and guidewire were then introduced through a small scalpel incision directly into the common femoral artery, at which time a bolus of 5,000 to 10,000 U of heparin was administered intravenously. During catheter exchanges not involving the introducer sheath, hemostasis was maintained directly with umbilical tapes proximal and distal to the arterial entry site, and digital compression of the entry site. Small amounts of local bleeding were managed with vacuum suction.

Balloon valvuloplasty was performed using a 9Fr catheter (Mansfield Scientific) with a balloon constructed of polyethylene. The balloon was 15, 18, 20 or 25 mm in diameter and 3.0 or 5.5 cm in length. In most patients, single balloon valvuloplasty was performed using 1, rather than a series, of single balloons and this single balloon was typically 20 mm in diameter and 5.5 cm in length. Likewise, attempts at single balloon valvuloplasty were typically discontinued if an optimal result was not achieved with the 20 mm, 5.5 cm balloon, although in a few of the earlier patients, additional attempts were made using a 25 mm, 3.0 cm balloon. Up to 3 dilations, each 10 to 20 seconds in duration, were performed with each single balloon.

Balloon catheters were introduced directly into the arteriotomy via a 260 cm, 0.038 inch exchange wire (Cook), the distal tip of which was fashioned into an exaggerated "J". After each series of dilations with a single balloon catheter was completed, it was exchanged for an 8FR A-2 multipurpose or 8Fr pigtail catheter (Cordis); the latter was introduced along with a 12Fr introducer sheath (Universal Medical Instruments) to assist hemostasis during hemodynamic assessment.

Technique of dual balloon valvuloplasty: The 260 cm "J"-tipped exchange wire was reintroduced through the diagnostic catheter, which was then removed (Figure 1). A 9Fr angioplasty guide catheter (Schneider-Shiley) or an 8Fr double lumen catheter (Mansfield), which can accommodate two 0.038 inch guidewires, was then introduced over the exchange wire into the left ventricle. A second 260 cm "J"-tipped guidewire was then advanced through the guide catheter into the left ventricle. The guide catheter and introducer sheath were then removed. Because initial applications of the dual balloon technique produced hypotension and bradycardia that appeared to be vagally mediated at the time of dual balloon inflation, subsequent patients routinely received atropine sulfate, 0.8 mg, intravenously at this point. Two new balloon catheters were then introduced in tandem fashion via the exchange wires, up to the level of the dia-

phragm. At this point, any small air bubbles were reevacuated from the syringes used to inflate the balloon (the balloons were otherwise filled with a 2:1 mixture of saline and meglumine diatrizoate). The balloons were then advanced together into the ascending aorta and across the aortic valve into the left ventricle. After proper position was established across the valve, the balloons were inflated simultaneously for 5 to 15 seconds, after which they were withdrawn into the descending aorta. In most patients only a single pair of inflations was performed, although in occasional patients dual balloon inflation was performed a second or third time. One balloon catheter with its accompanying guidewire was then removed, taking special care to apply negative pressure during the "delivery" of the balloon through the arteriotomy. The second exchange wire was left in place across the aortic valve while the remaining balloon catheter was exchanged for a diagnostic catheter and introducer sheath. Following completion of the postvalvuloplasty hemodynamic recordings and aortic root angiography, the catheter and sheath were removed. At the completion of the procedure, arteriotomy was extended proximally and distally to inspect for intimal trauma and then closed using a continuous suture of 5-0 prolene. The superficial fascia and skin were then closed in routine fashion.

Results

Clinical data including hemodynamic and angiographic findings in the 16 patients undergoing in vivo dual balloon valvuloplasty are summarized in Tables I and II and Figures 2 through 5.

Hemodynamic findings: Peak aortic valve gradient decreased from 79 ± 8 mm Hg (mean ± standard error of the mean) before valvuloplasty to 57 ± 7 after single balloon valvuloplasty ($p < 0.0005$) (Figure 2). Likewise, mean aortic valve gradient decreased from 56 ± 5 before to 42 ± 5 mm Hg ($p < 0.0005$) (Figure 3). Cardiac output did not change significantly (Figure 4). Calculated aortic valve area [10] increased from 0.45 ± 0.04 to 0.57 ± 0.05 cm^2 ($p < 0.0005$) (Figure 5).

Dual balloon valvuloplasty accomplished a further diminution in peak gradient from 57 ± 7 after single balloon valvuloplasty to 36 ± 4 mm Hg after double balloon valvuloplasty ($p < 0.0005$). Mean gradient decreased from 42 ± 5 to 27 ± 3 mm Hg ($p < 0.0005$). Cardiac output did not change significantly. Finally, calculated aortic valve area increased from 0.57 ± 0.05 after single balloon valvuloplasty to 0.77 ± 0.06 cm^2 after double balloon valvuloplasty ($p < 0.0005$).

The percent change in peak and mean gradients, cardiac output and aortic valve area are listed in Table II. The percent changes in peak and mean gradients and cardiac output after dual balloon valvuloplasty were *not* significantly different from the percent

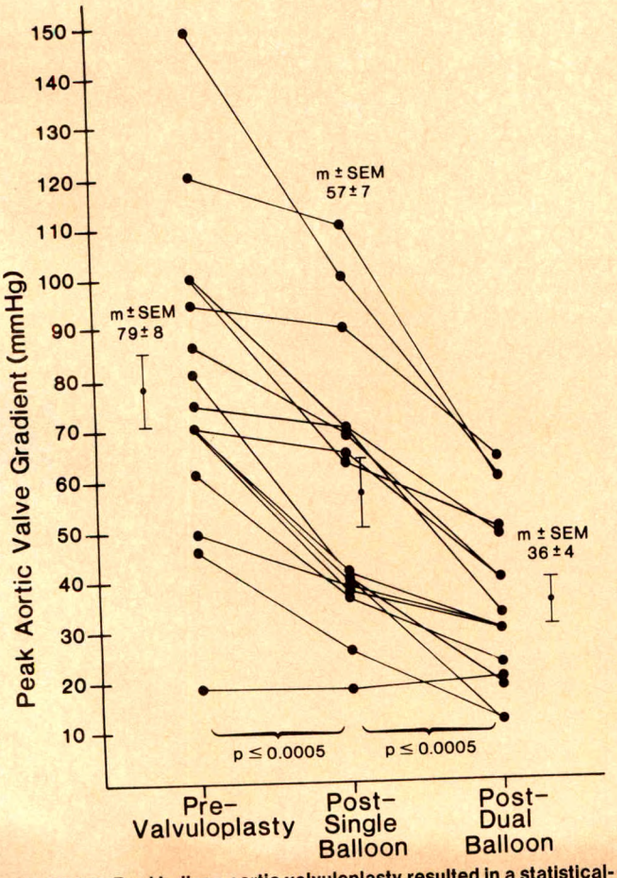

FIGURE 2. Dual balloon aortic valvuloplasty resulted in a statistically significant supplementary reduction in peak gradient beyond that achieved with a single balloon.

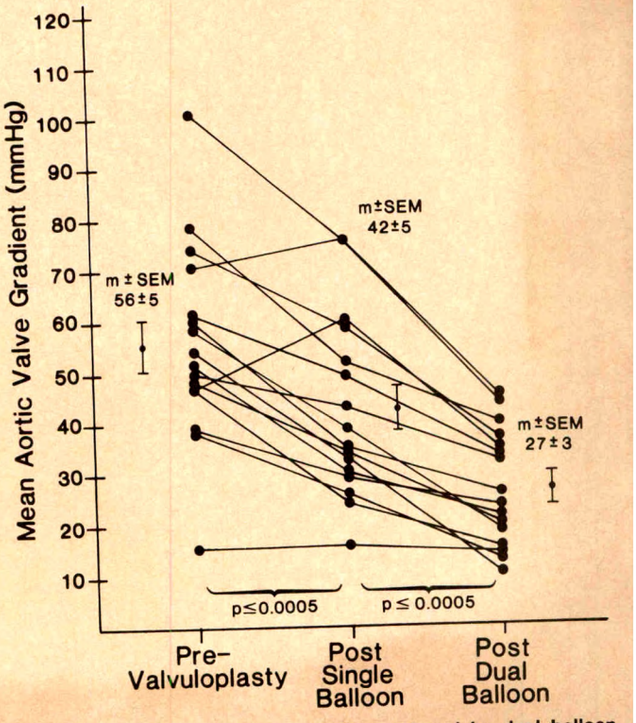

FIGURE 3. Mean gradient was further reduced by dual balloon inflation following completion of single balloon valvuloplasty.

change observed after single balloon valvuloplasty. That is, the magnitude of supplementary hemodynamic improvement achieved using 2 balloons was equivalent to that achieved with 1 or a series of single balloons. As a result of the severely diminished prevalvuloplasty aortic valve area, however, the percent change in calculated aortic valve area after dual balloon valvuloplasty was significantly ($p < 0.02$) greater than the percent improvement in valve area observed after single balloon dilation.

Aortic regurgitation: Patients were examined for aortic regurgitation by auscultation, Doppler ultrasound or aortic root angiography before and after the valvuloplasty procedure, but not between single and dual balloon valvuloplasty. By auscultation, aortic regurgitation was either absent or unchanged in all 16 patients. On Doppler ultrasound examination, no patient had new or more aortic regurgitation. Of 8 patients in whom aortic root angiography was performed after valvuloplasty, only 1 had evidence of new or increased (0 to "trace") aortic regurgitation.

In 1 patient, the only patient in whom we have repeated balloon valvuloplasty because of restenosis after an initially successful procedure, laceration of the common femoral artery occurred during removal of the balloon catheters following completion of dual valvuloplasty. The same artery was used for first (single) and second (single and dual) valvuloplasty procedures. Inspection of the artery at the time of surgical repair disclosed a site of focal, fibrotic constriction near the laceration. This constriction presumably resulted from the previous cutdown/repair and may have predisposed to the laceration at the time of the repeat dilation. In a second patient with mitral stenosis as well as AS, cardiac tamponade developed approximately 1.5 hours after a hemodynamically successful procedure. The patient was taken to the operating room but failed to survive combined aortic and mitral valve replacement after repair of a perforated left ventricle.

Discussion

Despite the documented short-term efficacy of aortic balloon valvuloplasty, certain limitations remain. In the majority of patients reported to date, varying degrees of AS typically persist. Although it is clear that symptomatic improvement may occur in association with even a small increase in calculated orifice area, the extent to which the threat of sudden death is diminished when important valvular stenosis persists remains unknown.[11] Further, preliminary follow-up data have demonstrated that the hemodynamic results obtained immediately after valvuloplasty are by no means permanent, even during the first 6 months of follow-up. Whether the magnitude of hemodynamic improvement obtained at the time of the original valvuloplasty is the principal determinant of restenosis—as has been suggested in the case of pulmonary valvular stenosis[12]—also remains unknown. It is clear that modifications in catheter design and technique are required.

The data from the 16 patients described in the present study indicate that use of the dual balloon technique may improve the hemodynamic results that can be accomplished with 1 or a series of single balloons in selected adults with calcific AS. The dual balloon technique has been used by previous investigators to treat a variety of valvular and congenital lesions

Khan,[13] Radtke,[14] Rao[12] and their co-workers used the dual balloon technique for children in whom the angiographic diameter of the pulmonary valve anulus was ≥20 mm. Moore et at[15] used dual balloon valvuloplasty to treat an infant with recoarctation of the aorta. Al Zaibag et al[16] and others[17,18] have demonstrated that simultaneous inflation of 2 balloons accomplished a hemodynamic result that is generally superior to that observed with single balloon valvuloplasty.

The largest experience with the dual balloon technique was reported by Mullins et al[19] who used the technique to treat 41 patients, mostly children, with stenosis of the pulmonic, aortic, mitral and tricuspid valves and vena cava. Mullins selected patients for the dual balloon approach when the anular diameter of the stenotic lesion was large relative to available balloon diameter or when technical considerations obviated the use of larger balloon catheters. The 41 patients included 14 with AS; although the age and extent of valvular calcification was not clarified for this subgroup, the dual balloon technique reduced peak transvalvular gradient from an average of 68 before to 24 mm Hg after dual balloon inflation. Two patients had either new or slightly more aortic regurgitation postversus prevalvuloplasty, and 2 had transient left bundle branch block.

Finally, Dorros et al[20] recently reported application of a combined brachial-femoral dual balloon technique in 10 patients, using a peripheral vascular angioplasty balloon (maximum diameter 12 mm) in combination with up to 20 mm valvuloplasty balloons. Successful valvuloplasty was achieved in all 10 patients, and aortic valve area increased from 0.56 ± 0.3 to 1.03 ± 0.6 cm^2 ($p < 0.05$).

No serious complications were reported among these previously reported patients treated with dual balloon valvuloplasty. Our experience with the present group of 16 patients is similar in that no complications were observed that were directly attributable to the dual balloon technique.

In contrast to our patients, however, none of the previous investigations included serial hemodynamic evaluation of single followed by dual balloon valvuloplasty in the same individual patients. The findings reported here thus support both the acute efficacy, as well as the safety, of the dual balloon technique. Whether such improvement in acute hemodynamic outcome will translate into a superior long-term result remains to be determined.

The proper combination of balloon diameters for dual balloon valvuloplasty remains uncertain. Butto et al[21] found that in the case of dual balloon pulmonary valvuloplasty, both balloons retain their circular shape without effacement as long as the diameters of the 2 balloons are within 10 mm of each other and the combined diameters do not exceed the native pulmonary valve anular diameter by 90%. Further, it seems rea-

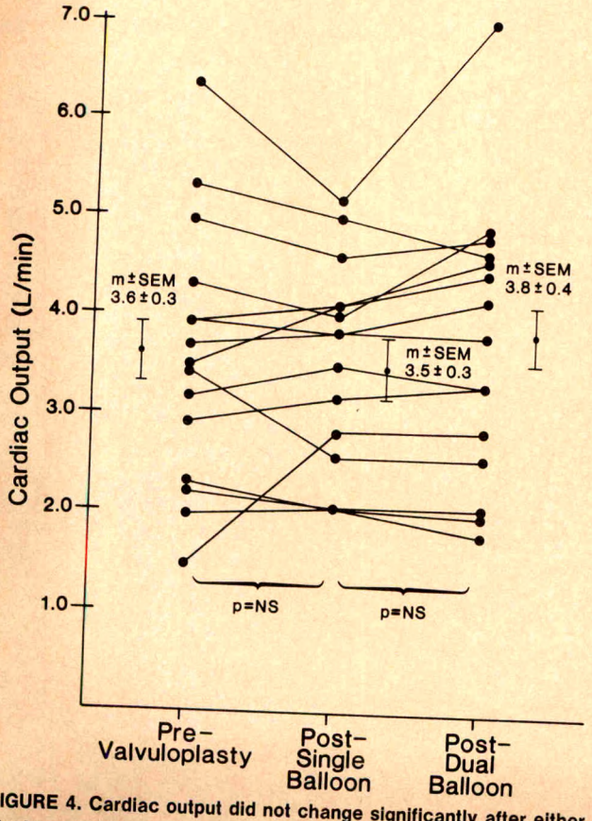

FIGURE 4. Cardiac output did not change significantly after either single or dual balloon valvuloplasty.

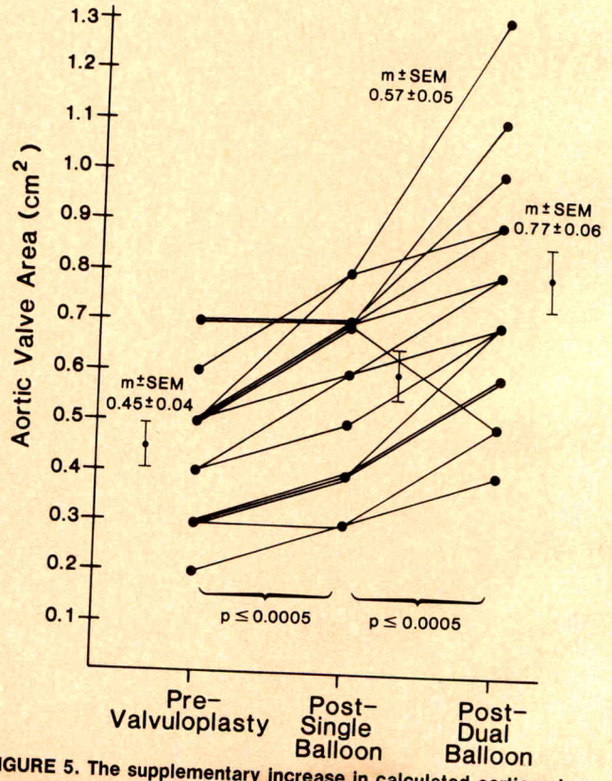

FIGURE 5. The supplementary increase in calculated aortic valve area accomplished with dual balloon dilation was highly statistically significant compared to that achieved with single balloon inflation.

sonable to use a combined diameter that exceeds that of the largest single balloon employed. How much in excess of 20 mm diameter (or 314 mm^2 in corresponding cross-sectional area) the combined balloon diameter/area should be must represent a compromise between efficacy and safety. Mullins et al[19] have recommended that for dual balloon aortic valvuloplasty, the sum of the inflated diameters should equal 1.2 or 1.3 times the aortic valve anular diameter. Although we observed no serious complications, Ring et al[22] have previously shown that if balloon diameter in the case of single balloon pulmonary valvuloplasty exceeds 30% of the native pulmonary valve diameter, hemorrhage into the right ventricular myocardium may occur. We are likewise aware of at least 1 published report[23] and 1 unpublished (personal communication, Mansfield Scientific) of anular rupture associated with single balloon valvuloplasty. Thus, the upper safe limit of balloon diameter/area—whether single or double—remains to be determined.

Addendum: Since the initial submission of this manuscript, we have used the dual balloon technique in 5 additional patients with similar results. The most recent application was performed using an exclusively percutaneous approach, made possible by the availability of lower profile balloon catheters (up to 20 mm diameter [Mansfield Scientific]) that can be introduced and removed via a 12Fr sheath. In the case of this 91-year-old woman, 18 and 20 mm balloons were passed simultaneously without complications via the right and left femoral arteries, increasing aortic valve area from 0.49 to 0.82 cm^2.

Effect of Mitral Regurgitation on Diastolic Filling with Left Ventricular Hypertrophy

M. ABUBAKR SHAIKH, MD, and STEVEN J. LAVINE, MD

Earlier studies have suggested that mitral regurgitation (MR) augments early left ventricular (LV) diastolic filling. To determine whether MR affects early diastolic filling in patients with abnormal diastolic filling, transmitral pulsed-wave Doppler recordings were used to study 32 normal subjects, 21 patients with LV hypertrophy, 23 with LV hypertrophy and MR and 15 patients with MR. Patients with MR had increased peak early filling velocities (MR 108 ± 27 cm/s, normal 80 ± 16 cm/s, $p < 0.01$), peak atrial filling velocities (MR 72 ± 18 cm/s, normal 55 ± 12 cm/s, $p < 0.05$) and increased deceleration rates (MR 5.0 ± 1.9 m/s^2, normal 3.5 ± 1.2 m/s^2, $p < 0.05$). Patients with LV hypertrophy had reduced peak early filling velocities (69 ± 14 cm/s, $p < 0.05$) and increased peak atrial filling velocities (83 ± 16 cm/s, $p < 0.001$). There was also an increase in the atrial filling fraction and reduction in the rapid filling fraction as compared with normal patients. Patients with LV hypertrophy and MR had increased peak early filling velocities (98 ± 26 cm/s, $p < 0.01$ vs normal, $p < 0.001$ vs LV hypertrophy patients), increased atrial filling velocities (84 ± 27 cm/s, $p < 0.001$ vs normal), increased deceleration rates (4.4 ± 2.4 m/s^2, $p < 0.05$ vs normal) and a normal distribution of diastolic filling. Within the LV hypertrophy and MR group, diastolic filling parameters were similar when patients were subgrouped on the basis of auscultability of MR. MR augments early diastolic filling and may tend to normalize diastolic filling patterns in LV hypertrophy patients. The use of diastolic filling to evaluate diastolic function in patients with MR should be used with caution.

(Am J Cardiol 1988;61:590–594)

Enhanced early left ventricular (LV) diastolic filling has been reported in patients with mitral regurgitation (MR).[1,2] Presumably, enhanced early diastolic filling is the result of an increased left atrial-LV pressure gradient early in diastole, produced by the V wave of MR.[1,3,4] We hypothesized that MR may alter the LV diastolic filling pattern by enhancing early diastolic filling in patients with heart disease known to produce abnormal diastolic filling. Concentric LV hypertrophy due to a variety of causes is one such entity known to be associated with abnormal diastolic filling.[5–7] In the present study, we evaluated the diastolic filling patterns in patients with concentric LV hypertrophy, combined LV hypertrophy and MR, patients with MR and patients without heart disease using pulsed-wave Doppler recordings of transmitral flow velocity. Measurements of transmitral flow velocity had been found to be useful in characterizing diastolic filling.[8,9]

Methods

Patients: We reviewed the M-mode, 2-dimensional and Doppler recordings of all patients referred to the Noninvasive Laboratory by their primary care physicians between August 1985 and March 1986. From this review, the recordings of 91 patients with sinus rhythm received a detailed evaluation of diastolic function if they were assignable to 1 of 4 groups. Group 1 consisted of 32 patients who had a normal history, physical examination, electrocardiogram and echocardiogram (M-mode, 2-dimensional and Doppler). Patients with a history of hypertension, use of calcium antagonists or who had LV hypertrophy were excluded. The presence of LV hypertrophy was assessed by M-mode evidence of septal or posterior wall thickness ≥12 mm. Group 2 consisted of 21 patients referred for evaluation of LV systolic function who had evidence of LV hypertrophy, M-mode fractional shortening ≥30% and no heart disease revealed by history, physical ex-

amination, electrocardiogram or echocardiogram. All patients in group 2 had hypertension and were being treated. β blockers were being used by 7. Patients using calcium antagonists were excluded. Group 3 comprised 23 patients also referred for evaluation of LV systolic function, who fulfilled the criteria for group 2 but in addition presented evidence of MR detected by pulsed-wave Doppler. Hypertension was present and treated in 20 patients, aortic stenosis was found in 3 and β-blockers were being used by 8. The cause of MR was ascribed to mitral anular calcification in 8, mitral valve prolapse in 5, calcified papillary muscle in 1 and was undetermined in 10. MR was considered to be mild in 11 patients, moderate in 11 and severe in 1. MR was auscultable in 9 and nonauscultable in 14. Patients using calcium antagonists were excluded. Group 4 consisted of 15 patients with a history of chronic MR and evidence of MR by pulsed-wave Doppler who did not have LV hypertrophy or other evidence of heart disease as assessed by history, physical examination, electrocardiogram or echocardiogram. Patients with a history of hypertension or use of calcium antagonists were excluded from this group. MR was ascribable to anular calcification in 6, mitral valve prolapse in 4 and was undetermined in 5. MR was considered to be mild in 8 patients, moderate in 6 and severe in 1.

M-mode and two-dimensional echocardiograms: All 91 patients had M-mode and 2-dimensional studies performed with a 3.5 MHz transducer (IREX Meridian, Johnson and Johnson). Patients with regional wall-motion abnormalities were excluded from the study. From the parasternal short-axis-derived M-modes of the LV, the interventricular septal thickness, posterior wall thickness, end-diastolic and end-systolic dimensions were obtained according to the recommendations of the American Society of Echocardiography.[10] Fractional shortening was calculated in the standard manner.[10] LV mass index was obtained using the M-mode cube function method of Devereaux and Reichek.[11]

Doppler studies: Pulsed- and continuous-wave Doppler studies were performed with a combined 2-dimensional phased array scanner (IREX Meridian) and a continuous and range-gated pulsed-wave Doppler (2.0 and 3.0 MHz). Full velocity signals were recorded on a strip-chart recorder or on video tape with an effective paper speed of 75 mm/s. Patients were examined in the left lateral position with the transducer placed at the apex to visualize the apical 4-chamber or long-axis view. Sample volume locations within the left atrium were varied in order to make a careful search for holosystolic turbulent flow suggesting MR. The diagnosis of MR was made when holosystolic turbulent flow was found in the left atrium. The severity of MR was determined by mapping of the left atrium. Holosystolic flow disturbances found at the level of the valve or 1 cm above were considered to be mild. Flow disturbances between 1 cm above the mitral valve to the midportion of the left atrium were considered to be moderate. Flow disturbances found extending from the midportion of the left atrium to the left atrial posterior wall or into the pulmonary veins were considered to be severe. Transmitral flow recordings were obtained by placing the sample volume in the mitral orifice, close to the tips of the mitral leaflets in diastole. Flow velocity recordings were not corrected for the angle between the Doppler flow direction and assumed mitral flow direction because the angle was always <20° (<6% error).

Transmitral flow measurements: Figure 1 is a graphic illustration of a normal flow velocity recording of transmitral flow. For each transmitral flow measurement, 5 consecutive spectral tracings were evaluated and averaged using a hand-controlled joystick and a computer-based analysis package (IREX Meridian Measurement and Analysis, Johnson and Johnson). We obtained the peak rapid filling velocity and peak atrial filling velocity in cm/s. The peak rapid filling velocity divided by the peak atrial filling velocity was also obtained as an additional transmitral flow velocity measurement. The rapid filling period was defined as the time interval from the onset of mitral flow to the end of rapid filling. The end of rapid filling was determined as a discernible point in time following the peak rapid filling velocity when the flow velocity curve plateaus (diastasis) or at the point when the flow velocity begins to rise. Similarly, the atrial filling period was defined as the onset of atrial filling to the end of mitral flow. The onset of atrial filling was determined as the point when a rise in flow velocity following a plateau (diastasis) or as the point when the flow velocity tracing accelerates following the end of the rapid filling period. The diastolic filling period was defined as the time interval from the onset to the end of transmitral flow. In this study, a wall filter of 0.12 m/s was used. Because the wall filter in this instrument produced a "velocity cutoff" at 0.12 m/s, we extrapolated the spectral tracings perpendicularly to the

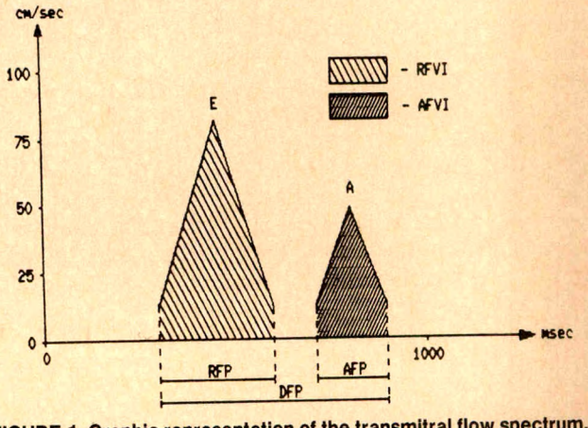

FIGURE 1. Graphic representation of the transmitral flow spectrum, which can be divided into a rapid filling period (RFP) and an atrial filling period (AFP). The area under the rapid filling spectrum (RFVI) or the atrial filling spectrum (AFVI) represents the amount of diastolic filling occurring during the rapid filling or atrial filling period. The peak rapid filling velocity (E) and the peak atrial filling velocity (A) are shown. DFP = diastolic filling period.

baseline. All timing measurements were taken from the baseline. The area beneath the spectral tracing was determined for the rapid filling, atrial filling and diastolic filling periods. Both rapid filling and atrial filling areas were divided by the diastolic filling area to generate a rapid filling and atrial filling fraction.

The deceleration rate following the peak rapid filling velocity was determined for each of the 4 groups. Briefly, the spectral tracing after the peak rapid filling velocity and before the atrial filling was examined and the deceleration slope obtained.

Statistical methods: Comparison among the 4 groups of patients for different echocardiographic and Doppler parameters were carried out by a 1-way analysis of variance. If statistical significance was obtained ($p < 0.05$), multiple comparison *t* tests were used to find out where significant differences existed. A p value of < 0.05 was considered significant. Data were expressed as mean ± standard deviation.

Results

The results of age, wall thickness, LV size, mass and function for normal subjects and patients with MR are listed in Table I. No significant differences were found between groups. Table II presents the parameters of diastolic filling for normal patients and those with MR. Both peak rapid filling velocity and peak atrial velocity were increased in the group with MR. There were no significant differences in any filling interval or in the rapid or atrial filling fraction. The deceleration rate was increased in the group with MR. Figure 2 shows a spectral tracing of transmitral flow for a normal subject (left) and a patient with MR (right). Both the early peak filling velocity and atrial filling velocity were increased as compared with the normal patient.

Table III summarizes the results of age, wall thickness, LV dimension, mass and function for normal subjects, patients with LV hypertrophy and patients with both LV hypertrophy and MR. The end-diastolic dimension was smaller in the group with LV hypertrophy as compared with the normal subjects. According to the entry criteria for this study, the posterior and septal wall thicknesses were increased in the groups with LV hypertrophy and LV hypertrophy with MR. In comparison with the normal subjects, LV mass was increased in the groups with LV hypertrophy and LV hypertrophy and MR. The diastolic filling parameters for normal subjects, patients with LV hypertrophy and those with LV hypertrophy and MR are listed in Table IV. The group with LV hypertrophy demonstrated a reduced peak rapid filling velocity, increased atrial filling velocity and reduced early peak rapid filling velocity/atrial filling velocity ratio as compared with the normal group. The rapid filling fraction was reduced while the atrial filling fraction was increased, in comparison with normal subjects. The group with LV

hypertrophy and MR demonstrated higher peak early filling velocities as compared with normal patients and the group with LV hypertrophy. The peak atrial filling velocity also was increased as compared with normal subjects and was similar to the group with LV hypertrophy. The peak early filling velocity/atrial filling velocity ratio was intermediate between normal subjects and patients with LV hypertrophy and significantly different from both. The rapid filling and atrial filling fractions were similar to those of normal subjects but significantly greater for the rapid filling fraction and significantly less for the atrial filling fraction as compared with the patients with LV hypertrophy. The deceleration rate was significantly greater in the group with LV hypertrophy and MR as compared with normal patients and those with LV hypertrophy. Figure 3 shows spectral tracings of transmitral flow for a patient with LV hypertrophy (left) and a patient with LV hypertrophy and MR (right). There was reduced early peak filling velocity and increased atrial filling velocity in the patient with LV hypertrophy as compared with the normal subject (Figure 2). In the patient with LV hypertrophy and MR, the early filling and atrial filling velocities were increased as compared with the normal group. The early filling velocity and atrial filling velocity peaks were nearly similar in height, that is, qualitatively different from the patient with LV hypertrophy.

Regarding the patients with MR and LV hypertrophy, 9 had auscultable MR and 14 nonauscultable MR. In the auscultable group, MR was mild in 4, moderate in 4 and severe in 1. In the nonauscultable group, 7 had mild and 7 had moderate MR. Table V lists the diastolic filling parameters for these 2 subgroups of patients and reveals no significant differences between them.

Discussion

In the present study, we sought to address the issue of whether MR could produce apparent normalization of early diastolic filling in patients with LV hypertrophy, an entity known to be associated with a high incidence of abnormal diastolic filling. In our patient selection process, we evaluated consecutive patient records meeting our criteria for patient inclusion. The use of β blockers in the patients with LV hypertrophy and LV hypertrophy with MR may have affected diastolic filling parameter determinations in those with blood pressure responses to therapy.[12] However, one-third of patients with LV hypertrophy and LV hypertrophy with MR were using β blockers as effective therapy for hypertension. Both groups had comparable degrees of MR and a similar distribution of etiologies (MR was mild in approximately 50%, which may explain why the end-diastolic dimension was not significantly increased as compared with normal subjects). Although no attempt at age matching was made, the mean group ages were comparable, minimizing age as a factor affecting diastolic filling.[13]

The data in this study indicate that peak early filling velocities, deceleration rate and atrial filling velocities were increased in patients with MR. Furthermore, diastolic filling was normally distributed between the rapid filling period and atrial filling period. Patients with LV hypertrophy had reduced peak early filling velocity, increased atrial velocity and a greater extent of filling during the atrial filling period. These findings in patients with LV hypertrophy were similar to those of previous studies.[5,14] Patients with LV hypertrophy and MR demonstrated increased peak early velocities, increased deceleration rate and elevated peak atrial velocities. The ratio of peak early to peak atrial velocity was intermediate between the normal subjects and the patients with LV hypertrophy. The distribution of

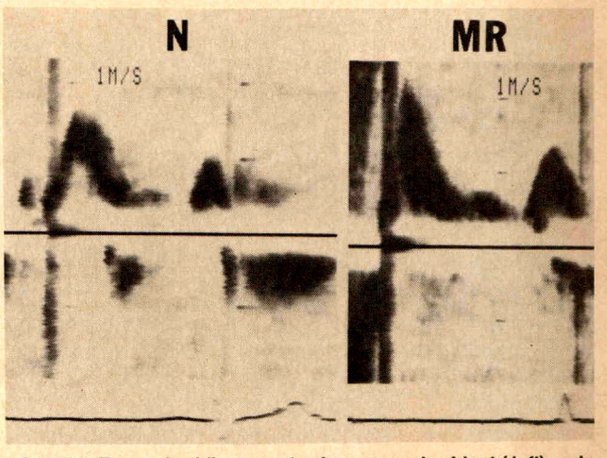

FIGURE 2. Transmitral flow spectra for a normal subject (*left*) and a patient with mitral regurgitation (*right*). There is an increase in both the peak rapid filling and peak atrial filling velocity. N = normal; MR = mitral regurgitation.

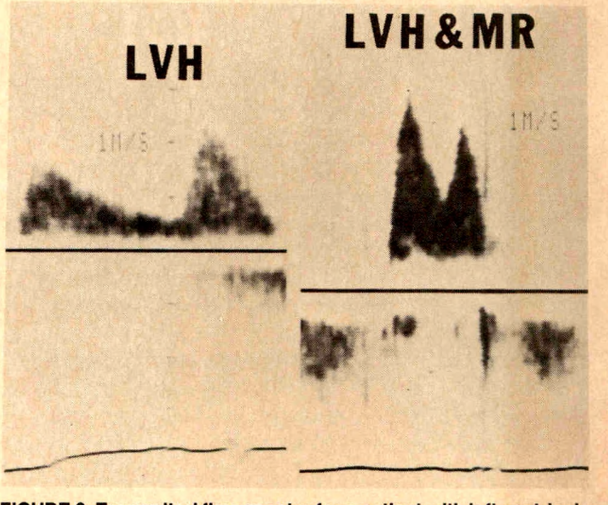

FIGURE 3. Transmitral flow spectra for a patient with left ventricular hypertrophy (*left*) and another with left ventricular hypertrophy and mitral regurgitation (*right*). The patient with left ventricular hypertrophy (LVH) demonstrates a reduced peak rapid filling velocity, increased atrial filling velocity and a ratio of peak rapid filling velocity/peak atrial filling velocity <1. The patient with left ventricular hypertrophy and mitral regurgitation (LVH&MR) had both increased peak rapid filling and peak atrial filling velocities as compared with normal subjects with a peak rapid filling velocity/peak atrial filling velocity >1.

TABLE V Diastolic Filling Parameters and Auscultability of Mitral Regurgitation

	Auscultable LVH & MR (n = 9)	Nonauscultable LVH & MR (n = 14)
Peak rapid filling velocity (cm/s)	104 ± 23	95 ± 22
Peak atrial velocity (cm/s)	86 ± 26	82 ± 29
E/A	1.3 ± 0.4	1.2 ± 0.4
Rapid filling fraction (%)	0.64 ± 0.16	0.66 ± 0.13
Atrial filling fraction (%)	0.36 ± 0.10	0.34 ± 0.12

Abbreviations as in Tables II and III.

diastolic filling was similar to that of normal subjects. The group with LV hypertrophy and MR was comparable in every way to the patients with LV hypertrophy, save for the presence of mitral regurgitation. Auscultability was not associated with a greater severity of MR, nor did it affect the diastolic filling characteristics as compared with those patients in which MR was not audible.

The data from patients with MR was comparable with M-mode echocardiographic and ventriculographic data previously reported in 2 studies,[1,2] both having reported an increase in the peak rapid filling rate. The peak atrial filling rate was not evaluated in these studies, but the atrial contribution of diastolic filling was similar to that of normal subjects. Although no study has yet evaluated the combined MR and LV hypertrophy, 1 study in hypertrophic cardiomyopathy patients demonstrated increased early rapid filling velocity in the obstructive type characterized by a high proportion of patients with MR.[15] Furthermore, the presence of MR in patients with dilated cardiomyopathy has been suggested as a reason for normalized early rapid filling velocities[16] and peak rates of filling noted among them.[17]

The present study retrospectively assessed diastolic filling characteristics in patients who had LV hypertrophy with or without MR. The mechanisms for these findings, at best, can only be speculated without simultaneous left atrial and left ventricular pressure recordings. Because the rate and extent of early diastolic filling has been demonstrated to be dependent on the magnitude and time course of the transmitral gradient,[18] we can hypothesize that the increased rate of early diastolic filling was probably due to an increased transmitral gradient contributed by the V wave of MR. The rapid decline in left atrial pressure (and the left atrial-left ventricular pressure gradient) following the V wave may be responsible for the increased rates of deceleration noted in both patients with MR and LV hypertrophy with MR: an attractive explanation for both types of patient. As to why late filling velocities were enhanced in MR patients is unclear, but may reflect an increase in total filling volume. In patients with MR and LV hypertrophy, late diastolic filling velocities were increased and similar to velocities in patients with LV hypertrophy. This may relate more to the underlying hypertrophy, which has a tendency to produce increased late filling velocities.[5-7] The normalization of the rapid filling fraction may be secondary to most of the regurgitant volume returning to the LV in early diastole. The failure to further increase late diastolic velocities is unclear. However, without simultaneous left atrial, left ventricular pressures and left ventricular volume to assess transmitral gradient and compliance, these explanations are speculative.

Clinical implications: The use of diastolic filling parameters and in particular the E/A ratio can be quite misleading if MR is present, especially in patients with LV hypertrophy or coronary disease. Caution should be exercised in interpreting diastolic filling parameters as estimates of diastolic function in the presence of MR. As both gated blood pool scintigraphy and M-mode can be used to assess diastolic filling and both do not directly assess the presence of MR, diastolic filling analysis by these techniques can be misleading. Furthermore, the use of physical examination to exclude MR may not be accurate, considering that 14 of 23 patients had nonauscultable MR in this study. Transmitral Doppler assessment of blood velocity may be preferable to other methods to evaluate diastolic filling in that it may alert us to the presence of MR.

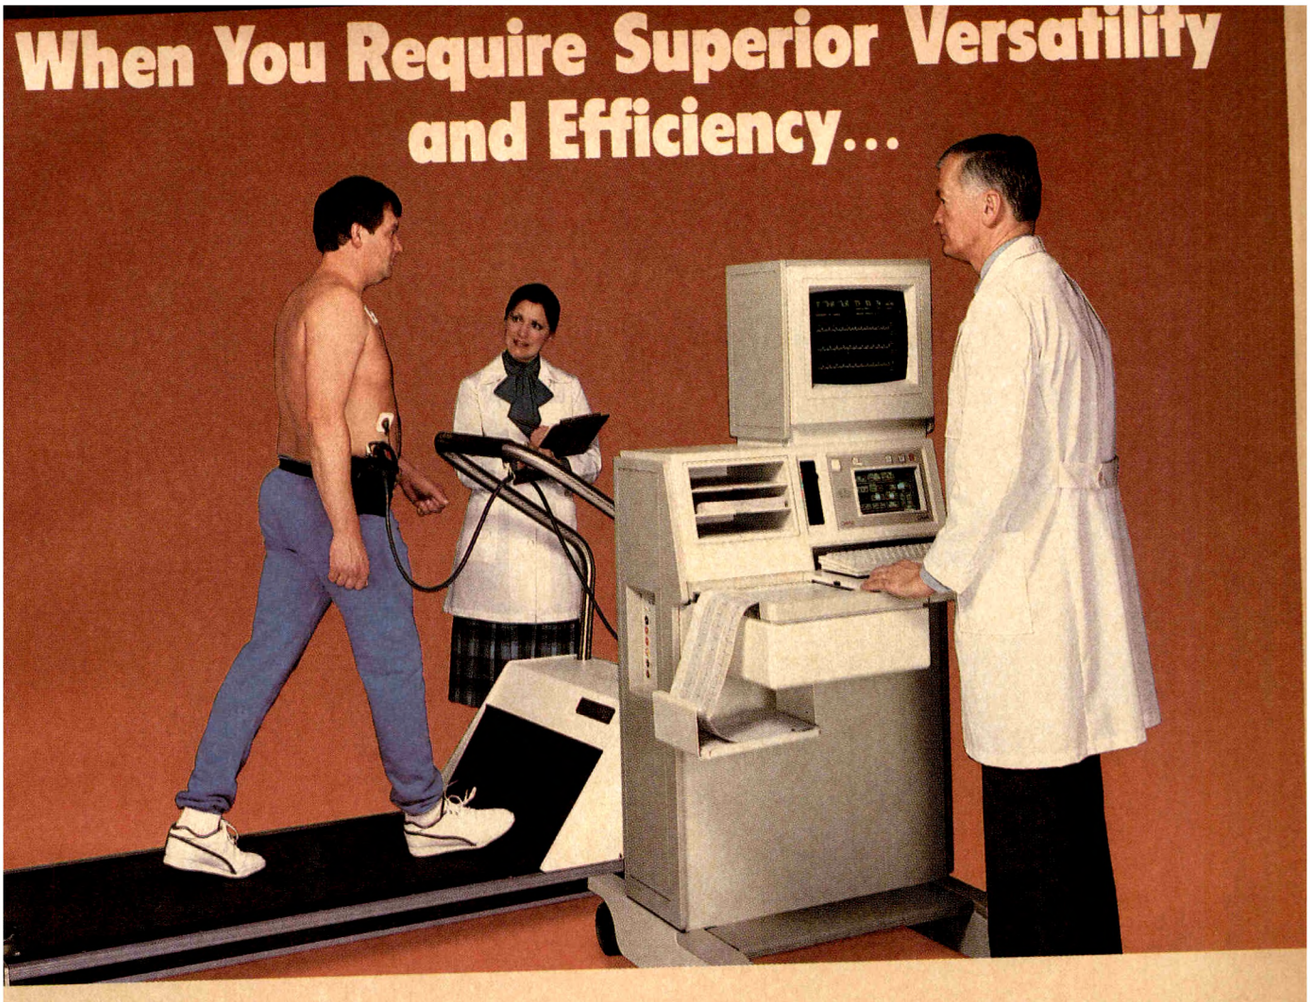
When You Require Superior Versatility and Efficiency...



.Choose Quinton's w Q5000 Premium ress Test System

ss testing in your facility poses gh challenges. You need ximum efficiency for routine ts with the versatility to handle eptions. You also need a system t can expand with your services. inton's top-of-the-line Q5000 ets your requirements.

ore Custom Information Less Time

hen you require quick customiza- n for diverse users and patients, Q5000 touch screen makes it nple. You can customize and rmanently store protocols, ocedures, and report content and aders. Print your reports without vision or easily edit them post test.

etrospective Analysis

he built-in hard disk stores up to 5 sets of patient data for conven- nt analysis. You can edit ST leasurements and print your final report, including trend graphs, with revised results. Reduce your storage space requirements by filing patient test data on IBM-compatible diskettes.

Expand Your Diagnostic Capabilities with Q-Plex™ I

The Q5000 and Q-Plex I, Quinton's **Pulmonary** Exercise System, operate as an integrated system, sharing stress test data to assist diagnosis of cardiopulmonary disorders.

Base Future System Expansion on the Q5000

The Q5000 communicates with two RS-232 compatible devices, including personal computers, for flexible expansion. For user and patient flexibility, the Q5000 controls our Premium Bicycle Ergometer and one of our Q-Series Premium Treadmills.

Anyone Can Operate It

All this versatility is there when you need it, but not in your way when you don't. The Q5000 runs tests automatically. Yet you can take complete control at any time—just touch one key.

Choose the Q5000, the system that meets all your stress testing requirements. For more information on this premier product, please call for our detailed brochure. . .

An A·H·ROBINS Company

Tambocor is indicated for the treatment of documented life-threatening ventricular arrhythmias, such as sustained V-tach.

Tambocor is also indicated for the treatment of patients with symptomatic NSVT and frequent PVCs. Because of the proarrhythmic effects of Tambocor, its uses in these less severe arrhythmias should be reserved for patients in whom, in the opinion of the physician, the benefits of antiarrhythmic treatment outweigh the risks.

For most patients, the better choice.

Joan Borra's symptomatic PVCs and NSVT have been successfully controlled by Tambocor® (flecainide acetate) B.I.D. for almost a year, and she experienced none of the problems characteristic of arrhythmia therapy. Tambocor has proven to be highly effective in study after study. In a multicenter clinical trial against quinidine, for example, Tambocor produced greater than 95% suppression of NSVT in 86% of patients.[1] In a 12-month follow-up to this trial, 94% of patients who remained on Tambocor had 100% suppression of NSVT.[2]

Tambocor is so well tolerated by most patients that discontinuation due to noncardiac adverse effects in a major multicenter study was only 5.4%.[3] Tambocor also has convenient b.i.d. dosing, making it easier to comply with in long-term use.

Tambocor has a low incidence of cardiac side effects in patients with symptomatic PVCs and NSVT. In a study of 1,330 patients treated with Tambocor, the overall incidence of proarrhythmia was 6.8%. In patients with PVCs, the incidence was 1.7% (8/470); in NSVT patients, 3.8% (18/469).[4] However, Tambocor should be used with caution and dosed differently in patients with sustained V-tach, particularly those with congestive heart failure or myocardial dysfunction. The incidence of cardiac adverse effects has been found to be substantially higher in these patients. Please see full prescribing information.

This exceptional record of efficacy, safety and tolerance has been borne out in six years' experience with more than 300,000 patients worldwide. It's no wonder that many physicians prefer Tambocor for the treatment of symptomatic PVCs and NSVT.

Please see following page for brief summary of full prescribing information.

TAMBOCOR® B.I.D.
(flecainide acetate)

The one to start with, the one to stay with.

TAMBOCOR® B.I.D.
(flecainide acetate)

Brief Summary. Consult the package insert for full prescribing information.

CONTRAINDICATIONS:
TAMBOCOR is contraindicated in patients with preexisting second- or third-degree AV block, or with right bundle branch block when associated with a left hemiblock (bifascicular block), unless a pacemaker is present to sustain the cardiac rhythm should complete heart block occur. TAMBOCOR is also contraindicated in the presence of cardiogenic shock or known hypersensitivity to the drug.

WARNINGS:
Proarrhythmic Effects. TAMBOCOR, like other antiarrhythmic agents, can cause new or worsened arrhythmias. Such proarrhythmic effects range from an increase in frequency of PVCs to the development of more severe ventricular tachycardia, e.g., tachycardia that is more sustained or more resistant to conversion to sinus rhythm, with potentially fatal consequences. In studies of TAMBOCOR, three fourths of proarrhythmic events were new or worsened ventricular tachyarrhythmias, the remainder being increased frequency of PVCs or new supraventricular arrhythmias. In patients with complex arrhythmias, it is often difficult to distinguish a spontaneous variation in the patient's underlying rhythm disorder from drug-induced worsening, so that the following occurrence rates must be considered approximations. Proarrhythmic effects were reported in 7% of patients treated with TAMBOCOR. Their frequency appears to be related to dose and to the underlying cardiac disease.
Among patients treated for sustained ventricular tachycardia (who frequently also had heart failure, a low ejection fraction, a history of myocardial infarction and/or an episode of cardiac arrest), the incidence of proarrhythmic events was 13% when dosage was initiated at 200 mg/day with slow upward titration, and did not exceed 300 mg/day in most patients. In early studies in patients with sustained ventricular tachycardia utilizing a higher initial dose (400 mg/day) the incidence of proarrhythmic events was 26%; moreover, in about 10% of the patients treated proarrhythmic events resulted in death, despite prompt medical attention. With lower initial doses, the incidence of proarrhythmic events resulting in death decreased to 0.5% of these patients. Accordingly, it is extremely important to follow the recommended dosage schedule (see Dosage and Administration).
Patients with less serious arrhythmias (chronic PVCs and nonsustained ventricular tachycardia) have experienced a lower rate of proarrhythmic events, about 3%, with 0.1% being fatal.
The relatively high frequency of proarrhythmic events in patients with sustained ventricular tachycardia and serious underlying heart disease, and the need for careful titration and monitoring, requires that therapy of patients with sustained ventricular tachycardia be started in the hospital. Hospitalization should also be considered for other patients with underlying structural heart disease (see Dosage and Administration).
Heart Failure. TAMBOCOR has a negative inotropic effect and may cause or worsen congestive heart failure (CHF), particularly in patients with cardiomyopathy, preexisting severe heart failure (NYHA functional class III or IV) or low ejection fractions (less than 30%). New or worsened CHF which might be attributed to TAMBOCOR therapy occurred in approximately 5% of patients studied in various trials. CHF developed rarely (1%) in patients who had no previous history of CHF. Exacerbation of preexisting CHF occurred more commonly in studies which included patients with class III or IV failure than in studies which excluded such patients. TAMBOCOR should be used cautiously in patients who are known to have a history of congestive heart failure or myocardial dysfunction. The initial dosage in such patients should be no more than 100 mg bid (see Dosage and Administration) and patients should be monitored carefully. Close attention must be given to maintenance of cardiac function, including optimization of digitalis, diuretic, or other therapy. In cases where CHF has developed or worsened during treatment with TAMBOCOR, the time of onset has ranged from a few hours to several months after starting therapy. Some patients who develop evidence of reduced myocardial function while on TAMBOCOR can continue on TAMBOCOR with adjustment of digitalis or diuretics, others may require dosage reduction or discontinuation of TAMBOCOR. When feasible, it is recommended that plasma flecainide levels be monitored. Attempts should be made to keep trough plasma levels below 0.7 to 1.0 μg/ml.
Effects on Cardiac Conduction. TAMBOCOR slows cardiac conduction in most patients to produce dose-related increases in PR, QRS, and QT intervals.
PR interval increases on average about 25% (0.04 seconds) and as much as 118% in some patients. Approximately one third of patients may develop new first degree AV heart block (PR interval ≥0.20 seconds). The QRS complex increases on average about 25% (0.02 seconds) and as much as 150% in some patients. Many patients develop QRS complexes with a duration of 0.12 seconds or more. In one study, 4% of patients developed new bundle branch block while on TAMBOCOR. The degree of lengthening of PR and QRS intervals does not predict either efficacy or the development of cardiac adverse effects. In clinical trials, it was unusual for PR intervals to increase to 0.30 seconds or more, or for QRS intervals to increase to 0.18 seconds or more. Thus, caution should be used when such intervals occur, and dose reductions may be considered. The QT interval widens about 8%, but most of this widening (about 60% to 90%) is due to widening of the QRS duration. The JT interval (QT minus QRS) only widens about 4% on the average. Significant JT prolongation occurs in less than 2% of patients. There has been one case of Torsade de Pointes-type arrhythmia associated with TAMBOCOR induced QT prolongation and bradycardia.
Clinically significant conduction changes have been observed at these rates: sinus node dysfunction such as sinus pause, sinus arrest and symptomatic bradycardia (1.2%), second-degree AV block (0.5%) and third-degree AV block (0.4%). An attempt should be made to manage the patient on the lowest effective dose in an effort to minimize these effects (see Dosage and Administration). If second- or third-degree AV block, or right bundle branch block associated with a left hemiblock occurs, TAMBOCOR therapy should be discontinued unless a temporary or implanted ventricular pacemaker is in place to ensure an adequate ventricular rate.
Sick Sinus Syndrome (Bradycardia-Tachycardia Syndrome). TAMBOCOR should be used only with extreme caution in patients with sick sinus syndrome because it may cause sinus bradycardia, sinus pause, or sinus arrest.
Effects on Pacemaker Thresholds. TAMBOCOR is known to increase endocardial pacing thresholds and may suppress ventricular escape rhythms. These effects are reversible if flecainide is discontinued. It should be used with caution in patients with permanent pacemakers or temporary pacing electrodes and should not be administered to patients with existing poor thresholds or nonprogrammable pacemakers unless suitable pacing rescue is available.
The pacing threshold in patients with pacemakers should be determined prior to instituting therapy with TAMBOCOR, again after one week of administration and at regular intervals thereafter. Generally threshold changes are within the range of multiprogrammable pacemakers and, when these occur, a doubling of either voltage or pulse width is usually sufficient to regain capture.
Electrolyte Disturbances. Hypokalemia or hyperkalemia may alter the effects of class I antiarrhythmic drugs. Preexisting hypokalemia or hyperkalemia should be corrected before administration of TAMBOCOR.

PRECAUTIONS:
Drug Interactions. TAMBOCOR has been administered to patients receiving digitalis preparations or beta-adrenergic blocking agents without adverse effects. During administration of multiple oral doses of TAMBOCOR to healthy subjects stabilized on a maintenance dose of digoxin, a 13% ± 19% increase in plasma digoxin levels occurred at six hours postdose.
In a study involving healthy subjects receiving TAMBOCOR and propranolol concurrently, plasma flecainide levels were increased about 20% and propranolol levels were increased about 30% compared to control values. In this formal interaction study, TAMBOCOR and propranolol were each found to have negative inotropic effects; when the drugs were administered together, the effects were additive. The effects of concomitant administration of TAMBOCOR and propranolol on the PR interval were less than additive. In TAMBOCOR clinical trials, patients who were receiving beta blockers concurrently did not experience an increased incidence of side effects. Nevertheless, the possibility of additive negative inotropic effects of beta blockers and flecainide should be recognized.
Flecainide is not extensively bound to plasma proteins. In vitro studies with several drugs which may be administered concomitantly showed that the extent of flecainide binding to human plasma proteins is either unchanged or only slightly less. Consequently, interactions with other drugs which are highly protein bound (e.g., anticoagulants) would not be expected. TAMBOCOR has been used in a large number of patients receiving diuretics without apparent interaction. Limited data in patients receiving known enzyme inducers (phenytoin, phenobarbital, carbamazepine) indicate only a 30% increase in the rate of flecainide elimination. In healthy subjects receiving cimetidine (1 gm daily) for one week, plasma flecainide levels increased by about 30% and half-life increased by about 10%.
When amiodarone is added to flecainide therapy, plasma flecainide levels may increase two-fold or more in some patients, if flecainide dosage is not reduced. (See Dosage and Administration.)
There has been little experience with the coadministration of TAMBOCOR and either disopyramide or verapamil. Because both of these drugs have negative inotropic properties and the effects of coadministration with TAMBOCOR are unknown, neither disopyramide nor verapamil should be administered concurrently with TAMBOCOR unless, in the judgement of the physician, the benefits of this combination outweigh the risks. There has been too little experience with the coadministration of TAMBOCOR with nifedipine or diltiazem to recommend concomitant use.
Carcinogenesis, Mutagenesis, Impairment of Fertility. Long-term studies with flecainide in rats and mice at doses up to about eight times the usual human dose of 8 mg/kg/day (assuming patient weight of 50 kg) have not revealed any compound-related carcinogenic effects. Mutagenicity studies (Ames test, mouse lymphoma and in vivo cytogenetics) did not reveal any mutagenic effects. A rat reproduction study at doses up to 50 mg/kg/day (seven times the usual human dose) did not reveal any adverse effect on male or female fertility.
Pregnancy. Pregnancy Category C. Flecainide has been shown to have teratogenic effects (club paws, sternebrae and vertebrae abnormalities, pale hearts with contracted ventricular septum) and an embryotoxic effect (increased resorptions) in one breed of rabbit (New Zealand White) but not in another breed of rabbit (Dutch Belted) when given in doses about four times (but not three times) the usual human dose (assuming a patient weight of 50 kg). No teratogenic effects were observed in rats and mice given doses up to 50 and 80 mg/kg/day, respectively; however, delayed sternebral and vertebral ossification was observed at the high dose in rats. Because there are no adequate and well-controlled studies in pregnant women, TAMBOCOR should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.
Labor and Delivery. It is not known whether the use of TAMBOCOR during labor or delivery has immediate or delayed adverse effects on the mother or fetus, affects the duration of labor or delivery, or increases the possibility of forceps delivery or other obstetrical intervention.
Nursing Mothers. Limited data suggest that flecainide is excreted in human milk. Because of the drug's potential for serious adverse effects in nursing infants, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.
Pediatric Use. The safety and effectiveness of TAMBOCOR in children less than 18 years of age have not been established.
Hepatic Impairment. Since flecainide elimination from plasma can be markedly slower in patients with significant hepatic impairment, TAMBOCOR should not be used in such patients unless the potential benefits clearly outweigh the risks. If used, frequent and early plasma level monitoring is required to guide dosage (See Plasma Level Monitoring); dosage increases should be made very cautiously when plasma levels have plateaued (after more than four days).

ADVERSE EFFECTS:
The most serious adverse effects reported for TAMBOCOR, described in detail in Warnings section, were new or exacerbated ventricular arrhythmias which occurred in 7% of patients, and new or worsened congestive heart failure which occurred in approximately 5% of patients. In some patients, TAMBOCOR treatment has been associated with episodes of unresuscitatable ventricular tachycardia or ventricular fibrillation. There have also been instances of second- (0.5%) or third-degree (0.4%) AV block. Patients have developed sinus bradycardia, sinus pause, or sinus arrest, about 1.2% altogether (see Warnings). The frequency of most of these serious adverse events probably increases with higher trough plasma levels, especially when these trough levels exceed 1.0 μg/ml.
There have been rare reports of isolated elevations of serum alkaline phosphatase and isolated elevations of serum transaminase levels. These elevations have been asymptomatic and no cause and effect relationship with TAMBOCOR has been established. In foreign postmarketing surveillance studies, there have been rare reports of hepatic dysfunction including reports of cholestasis and hepatic failure, and extremely rare reports of blood dyscrasias. Although no cause and effect relationship has been established, it is advisable to discontinue TAMBOCOR in patients who develop unexplained jaundice or signs of hepatic dysfunction or blood dyscrasias in order to eliminate TAMBOCOR as the possible causative agent.
Incidence figures for other adverse effects are based on a multicenter efficacy study, utilizing starting doses of 200 mg/day with gradual upward titration to 400 mg/day. Patients were treated for an average of 4.7 months, with some receiving up to 22 months of therapy. In this trial, 5.4% of patients discontinued due to non-cardiac adverse effects.

Table 1
Most Common Adverse Effects in Patients Treated With TAMBOCOR in the Multicenter Study

	Incidence in All	Incidence by Dose During Upward Titration		
Adverse Effect	429 Patients at Any Dose	200 mg/ Day (N=426)	300 mg/ Day (N=293)	400 mg/ Day (N=100)
Dizziness*	18.9%	11.0%	10.6%	13.0%
Visual Disturbance†	15.9%	5.4%	12.3%	18.0%
Dyspnea	10.3%	5.2%	7.5%	4.0%
Headache	9.6%	4.5%	6.1%	9.0%
Nausea	8.9%	4.9%	4.8%	6.0%
Fatigue	7.7%	4.5%	4.4%	3.0%
Palpitation	6.1%	3.5%	2.4%	7.0%
Chest Pain	5.4%	3.1%	3.8%	1.0%
Asthenia	4.9%	2.6%	2.0%	4.0%
Tremor	4.7%	2.4%	3.4%	2.0%
Constipation	4.4%	2.8%	2.1%	1.0%
Edema	3.5%	1.9%	1.4%	2.0%
Abdominal Pain	3.3%	1.9%	2.4%	1.0%

*Dizziness includes reports of dizziness, lightheadedness, faintness, unsteadiness, near syncope, etc.
†Visual disturbance includes reports of blurred vision, difficulty in focusing, spots before eyes, etc.

In a trial in ambulatory patients with frequent premature ventricular complexes and nonsustained ventricular tachycardia utilizing a starting dose of 400 mg/day and a maintenance dose of 400-600 mg/day, the incidence of these adverse experiences was similar, except for dizziness (32%) and visual disturbances (28%).
The following additional adverse experiences, possibly related to TAMBOCOR therapy and occurring in 1% to less than 3% of patients, have been reported in acute and chronic studies: *Body as a Whole*—malaise, fever; *Cardiovascular*—tachycardia, sinus pause or arrest; *Gastrointestinal*—vomiting, diarrhea, dyspepsia, anorexia; *Skin*—rash; *Visual*—diplopia; *Nervous System*—hypoesthesia, paresthesia, paresis, ataxia, flushing, increased sweating, vertigo, syncope, somnolence, tinnitus; *Psychiatric*—anxiety, insomnia, depression.
The following additional adverse experiences, possibly related to TAMBOCOR, have been reported in less than 1% of patients: *Body as a Whole*—Swollen lips, tongue and mouth; arthralgia, bronchospasm, myalgia; *Cardiovascular*—angina pectoris, second-degree and third-degree AV block, bradycardia, hypertension, hypotension; *Gastrointestinal*—flatulence; *Urinary System*—polyuria, urinary retention; *Hematologic*—leukopenia, thrombocytopenia; *Skin*—urticaria, exfoliative dermatitis, pruritus; *Visual*—eye pain or irritation, photophobia, nystagmus; *Nervous System*—twitching, weakness, change in taste, dry mouth, convulsions, impotence, speech disorder, stupor; *Psychiatric*— amnesia, confusion, decreased libido, depersonalization, euphoria, morbid dreams, apathy.

HOW SUPPLIED:
TAMBOCOR is supplied as white, round, scored tablets containing 100 mg of flecainide acetate and embossed with RIKER on one side and TR 100 on the other side.

Manufactured by:
Riker Laboratories, Inc./3M
St. Paul, Minnesota 55144

Noninvasive Assessment of Hemodynamic Responses to Exercise in Pulmonary Regurgitation After Operations to Correct Pulmonary Outflow Obstruction

GERALD R. MARX, MD, RICHARD W. HICKS, PhD, HUGH D. ALLEN, MD, and STANLEY J. GOLDBERG, MD

The influence of pulmonary regurgitation (PR) on exercise capacity is unknown. The hemodynamic responses to exercise in postoperative patients with PR was determined using Doppler-measured regurgitant fraction to indicate PR severity. Maximal heart rate, oxygen consumption and workload capacity were measured during upright cycle ergometry. Cardiac output was measured at rest and during submaximal supine cycle ergometry by pulsed Doppler echocardiography. Oxygen consumption was simultaneously measured and exercise factor was calculated as the change in cardiac output per change in oxygen consumption. Twenty-seven patients were compared with 17 age-, size- and sex-matched control subjects. Patients with PR had larger right ventricles ($p \leq 0.001$), lower heart rate response ($p \leq 0.05$), lower maximal oxygen consumption ($p \leq 0.005$) and lower workloads ($p \leq 0.005$) when compared with normal control subjects during maximal exercise testing. Exercise factor was the same for both groups. Patients with PR were then separated into mild, moderate and severe groups. Patients with mild PR had a normal response to exercise. However, patients with moderate and severe PR had lower maximal oxygen consumptions and maximal workloads than control subjects. Control, mild and moderate PR groups had similar exercise factors. Patients with severe PR had markedly low cardiac output responses. PR is associated with reduced exercise capability, which is related to the severity of the PR.

(Am J Cardiol 1988;61:595–601)

Pulmonary regurgitation (PR) is a common finding after surgery for critical pulmonary stenosis, tetralogy of Fallot or other defects that may require placement of a nonvalved conduit from the right ventricle to pulmonary arteries. Many of these patients have done well, but the influence of PR on exercise capacity is unknown. Inability to quantitate PR has impeded its investigation.[1] Pulsed Doppler echocardiography has recently been shown to accurately measure regurgitant fraction.[2] Magnitude of Doppler regurgitant fraction has compared well to clinical determinants of disease severity.[2] This study was designed to determine the hemodynamic responses to exercise in postoperative patients with PR using Doppler-measured regurgitant fraction to indicate severity of the PR.

Methods

Patient selection: Thirty-one patients with postoperative PR were chosen for study. Patients were at least 6 years of age and able to perform rigorous exercise testing. Patients were excluded if they had Doppler echocardiographic or catheterization findings of residual shunts, aortic, mitral or tricuspid regurgitation, stenosis or some combination of these. Patients with right ventricular outflow tract gradients >20 mm Hg, excluding peripheral stenosis, also were excluded. All patients had to be in sinus rhythm during exercise. An age- and sex-matched control group was also studied. Consent was obtained according to the guidelines of the University of Arizona Human Subjects Committee under an approved protocol.

Doppler echocardiography technique: Standard 2-dimensional pulsed and continuous-wave Doppler echocardiograms (BioSound ND 2600) were performed at rest on all subjects. M-mode scans for measurement of cavity size and wall thickness were obtained with cursor alignment guided by 2-dimensional imaging. Two-dimensional images of the left and right ventricles were obtained from a short-axis parasternal plane at the level of the mitral valve chordae tendinae. The M-mode cursor was placed through the right and left ventricles perpendicular to the ventricular septum. The site of ventricular septal patch placement was avoided in patients who had surgical ventricular septal defect closure. Right and left ventricular end-diastolic dimensions, left ventricular end-systolic dimensions and left ventricular percent fractional shortening were calculated according to standard guidelines of the American Society of Echocardiography.[3] All valves and right ventricular outflow tracts were interrogated by standard Doppler echocardiographic techniques for stenosis and regurgitation.[4,5] Regurgitation was considered insignificant if retrograde velocities were mapped only in a small area immediately proximal to the valves.[4,5]

Pulmonary regurgitant fraction was measured by a previously reported pulsed Doppler technique.[2] Pulmonary forward and regurgitant velocities were obtained proximal to the bifurcation in the midpulmonary artery, right ventricular outflow tract patch or conduit. In some patients the conduit or patch was poorly visualized, and the Doppler sample volume was placed in the area of anticipated regurgitant flow. The sample volume was then maneuvered until both simultaneous negative velocities of anterograde flow and positive velocities of retrograde flow with ≤30% velocity spread were obtained (Figure 1). Modal positive and negative Doppler velocities were separately digitized over 3 beats using a dedicated software program, digitizing pad and microcomputer.[4] The program determined positive and negative mean velocity by dividing the area under the time velocity curve by distance along the time axis. Percent pulmonary regurgitation was derived as regurgitant mean velocity/forward mean velocity × 100.

Ascending aortic velocities were measured from the suprasternal notch both at rest and during 50% supine submaximal exercise for determination of average aortic acceleration and cardiac output.[6] At rest, a 3.5-MHz transducer was used to image and perform Doppler velocity interrogation. A smaller 2.25-MHz right angle transducer was used during exercise.[6]

Average aortic acceleration, averaged over 3 beats, was calculated by a previously reported method as the peak velocity divided by the time to reach peak velocity.[7,8] Aortic diameter was measured from the suprasternal notch at the sample volume site above the sinuses of Valsalva.[9] Maximal aortic diameter measured at rest was used for flow calculation during submaximal exercise. Cardiac output (ml/min) was calculated as[4,6] mean velocity (cm/min) × cross-sectional area (cm^2).

Respiratory measurements: Expired respiratory gasses were continuously collected using a Wilmore-Costill 3-way valve system.[10] Fractional concentrations of oxygen and carbon dioxide were analyzed every 30 seconds using Beckman OM-11 and Godart Capnograph rapid gas analyzers.[10] Minute ventilation was measured using a Parkinson-Cowan CD-4 gas flow meter.[10] These measurements allowed calculation of oxygen consumption, carbon dioxide production and respiratory exchange ratio.

Exercise protocol: All subjects performed a graded maximal exercise test on a supine cycle ergometer (Spectrum Mode III) according to a standard protocol.[11] Maximal exercise capacity was also determined with patients pedaling an upright cycle in 34 of 44 subjects using the same protocol. (Ten young subjects were unable to reach the pedals.) This upright test allowed calculation of relative maximal endurance index, a measure of work performed indexed for size, sex and age.[11] The technician supervising the maximal exercise testing was blinded to patient's medical history and magnitude of PR.

An additional supine cycle exercise test was performed with the workload set to a level that corresponded to 50% of each individual's previously determined maximal oxygen consumption.[6] Oxygen consumptions and Doppler cardiac outputs were mea-

sured at rest and during the fifth minute of exercise at the predetermined workload. Exercise factor was calculated as the change in cardiac output between rest and exercise, divided by the simultaneous change in oxygen consumption.[6]

Statistical analysis: Grouped data for control and all PR subjects were compared using the unpaired Student *t* test. Data were then separated into control, mild, moderate and severe categories by magnitude of PR, according to a prior classification[2]: PR fraction <40% (mild), 40 to 60% (moderate) and >60% (severe). Statistical differences between groups were determined by analysis of variance and Scheffe post-hoc analyses. A p value of ≤ 0.05 was considered significant. Group data were expressed as mean and standard deviation.

Results

Control group versus entire pulmonary regurgitation group: Seventeen control subjects and 31 patients with PR were enrolled in the study. Four patients with PR did not meet minimal requirements for study and were excluded from the protocol, leaving 27 PR patients for data analysis (Table I). Control and PR groups were not significantly different in age, sex distribution and body surface area. Left ventricular end-diastolic dimension, percent fractional shortening and resting and exercise Doppler average aortic acceleration were not significantly different for both groups (Figure 2). The PR group had significantly larger right ventricles than control subjects ($p \leq 0.001$, Figure 2). The PR group also had significantly lower maximal heart rate response ($p \leq 0.05$), lower maximal oxygen consumption ($p \leq 0.005$) and lower workload performed during maximal exercise testing ($p \leq 0.005$, Figure 3). Exercise factor was not significantly different for both groups (Figure 3).

Control group versus mild, moderate and severe groups: *Population, age and size:* Data were then analyzed by separating subjects into mild, moderate and severe PR groups (Table I). The control group consisted of 17 subjects (mean age 12 years), mild group 9 patients (mean age 12 years), moderate group 10 patients (mean age 12 years) and severe group 8 patients (mean age 10 years). Age and size were not significantly different for all 4 groups.

Diagnoses in mild group: Five patients in the mild PR group had repair of tetralogy of Fallot. None required a transanular patch or conduit. Four patient had isolated valvar pulmonic stenosis. Three had surgical pulmonary valvotomies, and 1 patient underwent balloon dilation valvuloplasty. None of the 9 patients had significant peripheral pulmonic stenosis.

Diagnoses in moderate group: Six patients in the moderate PR group had repaired tetralogy of Fallot; 5 required a transanular patch. The 1 patient without a patch had significant bilateral peripheral pulmonic stenosis. Three patients had pulmonary valvotomies in the newborn period for critical valvar pulmonic stenosis; 2 required a second operation. One had a repeat valvotomy, and the other placement of a transanular patch. One patient had a nonvalved conduit after Damas-Stansel-Kaye repair for double-outlet right ventricle.

Diagnoses in severe group: Seven patients in the severe PR group had nonvalve conduits. Four of the 7 underwent recent cardiac catheterizations and all 4 had significant peripheral pulmonic stenosis. The eighth patient had transanular patch repair for tetralogy of Fallot and has not undergone postoperative catheterization.

Baseline data: *Magnitude of regurgitation:* Mean PR fraction was 22% (10.7 standard deviation [SD]) for the mild group; 48% (4.2 SD) for the moderate group; and 77% (5.9 SD) for the severe group, ($p \leq 0.001$). All 3 groups were significantly different from each other.

Right ventricle-to-aortic pressure ratio: Cardiac catheterization data were retrospectively reviewed for calculation of right ventricular-to-aortic pressure ratio in 18 (67%) patients. Mean right ventricular-to-aortic pressure ratio was 35% (7.4 SD) for the mild group (n = 6); 44% (10.1 SD) for the moderate group (n = 8); and

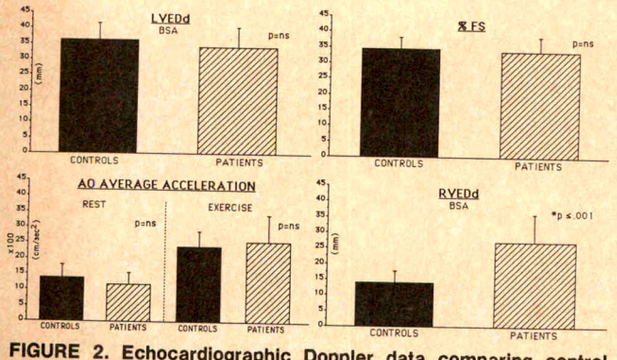

FIGURE 2. Echocardiographic Doppler data comparing control group versus entire pulmonary regurgitation group. Left ventricular end-diastolic dimension (LVEDd), left ventricular percent fractional shortening (%FS) and Doppler aortic (Ao) average acceleration at rest and exercise was similar for both groups. Patients had significantly larger right ventricular end-diastolic dimensions (RVEDd).

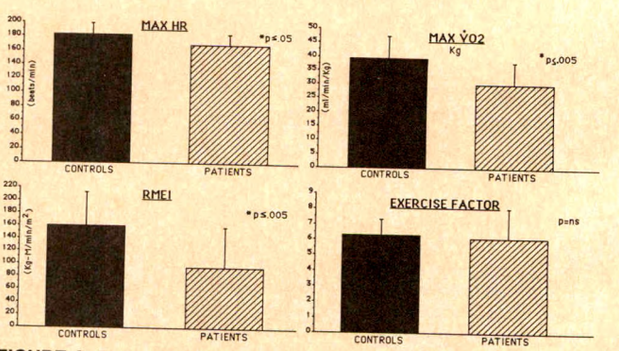

FIGURE 3. Exercise hemodynamics comparing control group with entire pulmonary regurgitation group. During maximal upright cycle ergometry patients had lower maximal heart rate (Max HR), oxygen consumption (max$\dot{V}O_2$) and workload (RMEI) than the control group. Exercise factor measured during submaximal exercise was not significantly different.

74% (18.7 SD) for the severe group (n = 4), ($p \leq 0.001$). The severe group was significantly different from both mild and moderate PR groups; the latter 2 groups were not significantly different from each other.

M-mode data: Mean left ventricular end-diastolic dimension indexed for body surface area and percent fractional shortening were not significantly different for the 4 groups (Figure 4). Mean right ventricular end-diastolic dimension was 14 mm/m^2 (3.6 SD) for the control group; 20 mm/m^2 (4.4 SD) for the mild group; 26 mm/m^2 (8.2 SD) for the moderate group; and 36 mm/m^2 (6.1 SD) for the severe group ($p \leq 0.001$). All groups were significantly different from each other (Figure 4).

Aortic average acceleration: Average resting and exercise aortic accelerations were not significantly different for all 4 groups (Figure 4).

Exercise data: Not all patients were tall enough to reach the pedals of the upright cycle ergometer. Comparison of maximal upright cycle testing data was made in 15 patients in the control group, 7 in the mild, 6 in the moderate and 6 in the severe PR groups.

Maximal heart rate: Mean maximal heart rate attained for the control group was 182 beats/min (17 SD); 178 (12 SD) for the mild group, 172 (15 SD) for the moderate group and 155 (11 SD) for the severe PR group ($p \leq 0.01$). Only the control and severe groups were significantly different from each other (Figure 5).

Maximal oxygen consumption: Mean maximal oxygen consumption was 39 ml/min/kg (7.9 SD) for the control group, 37 (8.2 SD) for the mild group, 28 (6.1 SD) for the moderate group and 25 (4.8 SD) for the severe PR group ($p \leq 0.005$). Both the moderate and severe groups were significantly different from control. The severe group was also significantly different from the mild group (Figure 5).

Relative maximal endurance index: Mean relative maximal endurance index for the control group was 160 kg-m/min/m^2 (52 SD), 154 (49 SD) for the mild group, 80 (34 SD) for the moderate and 43 (47 SD) for the severe group ($p \leq 0.001$). Both moderate and severe PR groups were significantly different from the control group (Figure 5).

Exercise factor: Mean exercise factor for the control group was 6.3 (1.0 SD), 6.5 (1.7) for the mild group, 7.6 (1.2) for the moderate group and 4.1 (1.0 SD) for the severe PR group ($p \leq 0.001$). The severe group was significantly different from the other 3 groups (Figure 5).

Discussion

Results of this study demonstrated that subjects with PR had lower maximal heart rate responses, lower maximal oxygen consumptions and lower maximal workload capacities during upright bicycle ergometry compared with normal control subjects. In addition, the magnitude of response was related to the degree of PR. Subjects with mild PR had normal hemodynamic responses to exercise. Subjects with moderate and severe PR had lower maximal oxygen consumptions and maximal workload capacities. Control, mild and moderate PR groups had similar increases in cardiac output per increase in oxygen consumption during submaximal exercise. However, some patients in the severe group had a markedly low cardiac output response. Patients with more severe PR had increased M-mode right ventricular end-diastolic dimensions. Right ventricular systolic pressures were increased at catheterization. The most severe PR occurred in patients who had pulmonary artery stenosis distal to their patches or nonvalved conduits.

Results of this study are consistent with those of others who have reported increased right ventricular size,[12] reduced radionuclide right ventricular ejection fraction[12] and decreased exercise capacity[13] in pa-

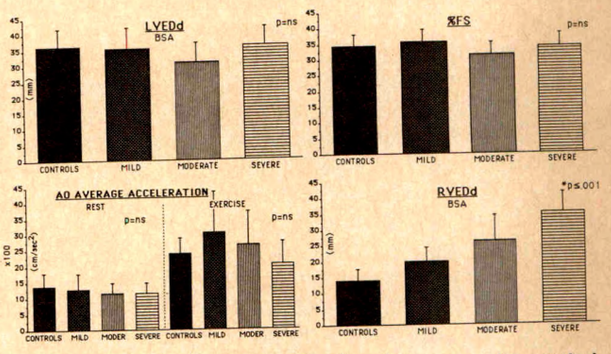

FIGURE 4. Echocardiographic Doppler data comparing control, mild, moderate and severe pulmonary regurgitation groups. Analysis of variance p values are shown in *upper right* of each panel. Left ventricular end-diastolic dimension (LVEDd); left ventricular percent fractional shortening (%FS) and Doppler aortic (Ao) average acceleration at rest and exercise were not significantly different for all groups. Right ventricular end-diastolic dimension was increased in relation to percent pulmonary regurgitation.

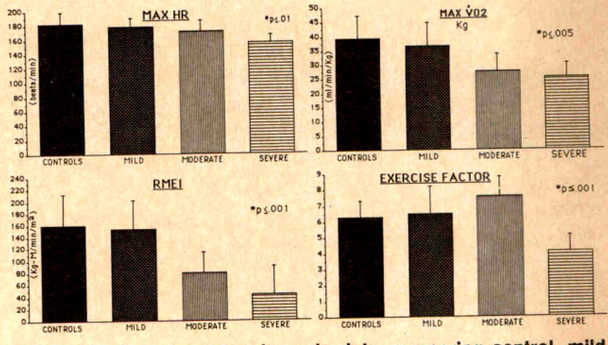

FIGURE 5. Exercise hemodynamic data comparing control, mild, moderate and severe pulmonary regurgitation groups. Analysis of variance p values are shown in *upper right* of each panel. During maximal upright cycle ergometry the severe group and lower maximal heart rate than controls. Moderate and severe groups had lower maximal oxygen consumption (Max $\dot{V}O_2$) than the control group; the severe group was also lower than the mild group. Moderate and severe groups had lower workload (RMEI) than the control group. The severe group had lower exercise factor during submaximal exercise than each of the other 3 groups.

tients with PR. Additionally, reduction in right ventricular size,[14,15] improved right ventricular function[14,15] and exercise capacity[14,15] and improvement in clinical findings of right heart failure[15,16] have been reported after pulmonary valve placement for severe PR. However, other investigators[17] have reported low exercise factor in postoperative tetralogy of Fallot patients regardless of the absence or presence of a pulmonary valve.

In this study Doppler measurement of percent PR assumed a constant diameter throughout the cardiac cycle. A previous study confirms the validity of this premise.[2] This calculation also appears valid in 15 of 27 subjects (56%) who had outflow tract patches or conduits. Nonetheless, the intent of this study was not to use measurement of Doppler PR fraction in absolute terms, but rather to separate subjects into broad categories of mild, moderate and severe PR.

M-mode-derived left ventricular end-diastolic dimensions and percent fractional shortening were not significantly different for all 4 groups. However, right ventricular volume overload causing paradoxical septal wall motion[18] and ventricular septal defect patches make absolute measurement of ventricular size difficult. Hence, reliance on comparison between groups of patients, and not on absolute values for ventricular size, is emphasized. In addition, percent fractional shortening has limitations as a determinant of ventricular function since it is both pre- and afterload dependent. An index for noninvasive measurement of ventricular function has been reported that is preload independent, incorporates afterload and is heart rate corrected. This index is the end-systolic wall stress/heart rate corrected velocity of fiber shortening relation.[19] Others have used this index to demonstrate that patients with conduit repair for transposition of the great arteries, ventricular septal defect and pulmonary stenosis have decreased left ventricular function.[20] Use of this index may uncover differences in left ventricular performance between pulmonary regurgitation patients.

Average aortic acceleration compares well with changes in dP/dt and dQ/dt under conditions of varying preload, heart rate and inotropic state in animals.[21] Average aortic acceleration has also been used to differentiate adult patients with myocardial dysfunction.[8] In our study, all patient groups had statistically similar average aortic accelerations at rest and at submaximal exercise, although the severe group tended to have a lower aortic acceleration during exercise.

An exercise factor of 7.2, measured at catheterization, has been reported in pediatric patients.[22] One study in normal preadolescent boys[6] measured cardiac output by pulsed Doppler during submaximal exercise and found an exercise factor of 6.4 (1.2 SD). In our study only 4 patients (all in the severe PR group) had exercise factors lower than 2 SD below the previously reported normal mean value. Two of these patients had right ventricular to aortic pressure ratios >70% at catheterization. Excessive patient motion and respiratory effort prevented obtaining adequate Doppler ascending aortic velocity traces at higher workloads. Hence, exercise factor and aortic acceleration were measured only at submaximal exercise. Measurement of exercise factor and aortic acceleration at higher workloads may have more clearly differentiated the patient groups.

Other variables, in addition to pulmonary regurgitation, may have contributed to the differences in patient groups. Patient age, age at surgery, type of repair and myocardial preservation could not be controlled between patient groups. The population was heterogeneous and included patients with different lesions. However, when we analyzed the data for tetralogy of Fallot patients alone, results were statistically similar to those for patients with other lesions.

In addition, hemodynamically significant PR did not appear to occur as an isolated event. Absence of a functional valve in the pulmonary position and elevated distal pulmonary pressure appear to be requirements for hemodynamically significant PR, regardless of the type of underlying defect. Elevated distal pulmonary pressure occurred in our study as a result of peripheral pulmonary stenosis, but presumptively could occur secondary to pulmonary parenchymal or pulmonary vascular obstructive disease. Decreased pulmonary flow to 1 or both lungs, and associated ventilation-perfusion abnormalities, may also have contributed to decreased exercise capacity.[13] As shown by catheterization data, available in two-thirds of the patients in this study, significant PR was associated with right ventricular hypertension. Decreased right ventricular ejection with exercise has been reported in patients with right ventricular hypertension from obstructed conduits alone.[23] In this study, patients with increasing severity of PR also had more right ventricular dilation. However, no direct measure of right ventricular systolic or diastolic function was made. Right ventricular dilation may have been an indicator of primary ventricular dysfunction related to large ventriculotomies for placement of noncontractile patches or conduits.[24] Additionally, the more dilated right ventricles may have adversely affected left ventricular diastolic function.[25] Similar to other investigators,[13] we do not believe that PR alone caused the abnormal response to exercise, but rather a constellation of findings associated with significant PR were the probable etiologies.

Many of our patients with moderate and severe PR were able to attend school and lead active lives. Although baseline Doppler echocardiograms demonstrated right ventricular dilation and increased regurgitant fractions, exercise testing most clearly differentiated the moderate and severe PR patients.

Acknowledgment: We would like to express our sincere appreciation to Cheryl Czaplicki for typing and editing the manuscript.

Results of the Modified Fontan Operation in Adults

RICHARD A. HUMES, MD, DOUGLAS D. MAIR, MD, CO-BURN J. PORTER, MD, FRANCISCO J. PUGA, MD, HARTZELL V. SCHAFF, MD, and GORDON K. DANIELSON, MD

The results of the modified Fontan procedure were examined in 77 patients 18 years of age and older who underwent operation at this institution between October 1973 and December 1986. This series represents 16% of the patients undergoing the modified Fontan operation during that period. Of the 77 patients (46 men and 31 women), 29 had tricuspid atresia, 30 had double-inlet ventricle and 18 had other complex lesions. There were 5 (6%) hospital deaths, compared with 67 (17%) for patients of all ages undergoing the Fontan operation during the same period. Patient age 18 years and older was not a significant risk factor. There were 8 late deaths. Detailed follow-up data were available on 61 (95%) survivors from 5 months to 12 years (mean 4 years) postoperatively. Fifty-seven (93%) of the patients were in New York Heart Association class I or II, 20 (33%) were taking no medication and 11 (18%) were taking digoxin alone. Seventeen (28%) patients complained of persistent ascites or edema. The study indicated that (1) the modified Fontan operation can be performed with low mortality in adults, (2) the long-term outcome is favorable and (3) persistent ascites or edema may be a problem in some patients.

(Am J Cardiol 1988;61:602–604)

Since the original description by Fontan and Baudet[1] in 1971 and subsequent modifications by Kreutzer et al[2] in 1973, the direct atrial-pulmonary arterial connection or Fontan operation has been used successfully to separate the pulmonary and the systemic circulations in patients who have a functional single ventricle. The results of the Fontan operation in younger patients have been examined previously. We examined the results of the modified Fontan operation in adults, specifically patients 18 years of age or older.

Methods

Patients: Between October 1, 1973, and December 31, 1986, 496 patients underwent a Fontan or modified Fontan operation at our institution. Seventy-seven of these patients (16%) were 18 years or older at the time of operation. The clinical records of these 77 patients were reviewed.

The ages of the 77 patients (46 men and 31 women) ranged from 18 to 42 years (mean 24). All patients had a cardiac catheterization performed at our institution or the referring institution before operation. The pulmonary artery pressure ranged from 8 to 44 mm Hg (mean ± standard deviation, 19.1 ± 8.5). The ventricular end-diastolic pressure ranged from 3 to 32 mm Hg (mean 13.8 ± 6.0), and the pulmonary arteriolar resistance ranged from 0.2 to 3.9 units · m^2 (mean 1.8 ± 1.0). Criteria for operability follow modified guidelines established by Choussat et al.[3] Evidence of pulmonary vascular disease (pulmonary arteriolar resistance >5.0 units · m^2) or markedly hypoplastic (not discretely stenotic) pulmonary arteries is considered to be a contraindication to a successful Fontan operation.

The patients were classified as having tricuspid atresia, double-inlet ventricle or other complex lesions (Table I)—a classification consistent with previous reports from our institution.[4,5] These anatomic variations are associated with a functional single ventricle in all patients.

Sixty-four (83%) patients had had a previous palliative procedure (Table II). The most frequent operation was a Blalock-Taussig (subclavian artery-pulmonary artery) anastomosis, and next in frequency was the Glenn (superior vena cava-pulmonary artery) procedure. Thirty patients had 1 previous operation; 28 had 2; and 6 had 3 or more.

The operative technique for the various modifications of the operation has been the subject of previous reports.[4,5] In our earliest experience, heterograft valves or valved conduits were placed in the inferior or the superior vena cava or the pulmonary artery. Such placement was done in 10 patients in our study. This technique was largely abandoned by 1980 because the valves were found to be unnecessary.

Postoperative management involved the routine use of inotropic agents such as dopamine and dobutamine. Afterload-reducing agents, such as sodium nitroprusside, were routinely used during the immediate postoperative period and were replaced with captopril (angiotensin-converting enzyme inhibitor) during the ambulatory recovery period. Digoxin, furosemide and

spironolactone were also routinely administered during the postoperative period. Atrial and ventricular epicardial wire electrodes were routinely placed at the time of surgery and were used for diagnostic monitoring of arrhythmias or pacing, as required.

Hospital mortality was defined as death either while in the hospital or <30 days after operation. Follow-up was obtained by direct patient contact (by telephone or in person), requesting the patient's current subjective condition, exercise tolerance, medications and ability to perform daily activities.

Results

There were 5 hospital deaths (6%). This rate is significantly less than the 17% for patients of all ages and the 19% in our entire experience for patients younger than 18 years old undergoing the Fontan operation ($p = 0.04$, Fisher's exact test). Four of the 5 deaths occurred before 1981. The hospital deaths occurred at 0 to 53 days after operation. The cause of death was sepsis in 2 patients and myocardial failure in 3 patients. There were no significant differences in preoperative pulmonary artery pressure, ventricular end-diastolic pressure, pulmonary arteriolar resistance, ventricular ejection fraction or age between operative survivors and nonsurvivors (unpaired *t* test). Hospital mortality occurred in 3 cases of double-inlet ventricle, 1 of tricuspid atresia, 1 of left atrial isomerism (polysplenia), common atrioventricular valve and anomalous systemic and pulmonary venous return. There were 8 late deaths, occurring at 33 days to 4 years (mean 2 years) postoperatively. The cause of the late deaths was myocardial failure in 3 patients, sudden death (suspected arrhythmia) in 2, and renal failure, hepatic failure and pulmonary hemorrhage in 1 each.

Four patients required replacement of the left atrioventricular valve at the time of the Fontan operation, and 2 patients underwent repair of the atrioventricular valve because of severe atrioventricular valve insufficiency. All patients who underwent valve replacement survived to be dismissed from the hospital. One patient who had valve replacement died suddenly of an unexplained cause at home >1 month postoperatively. One patient who had repair of a common atrioventricular valve died in the operating room.

One hospital death occurred, and there were 4 late deaths among adult patients receiving heterograft valves. Although valvular obstruction led to reoperation and removal of these valves in some patients, their use did not significantly affect early or late mortality.

The preoperative presence of a particular shunt or pulmonary artery band was not significantly related to mortality. None of the patients without previous operations (age range 18 to 40 years, mean 24) died while in the hospital, and to date all have survived. This finding, however, was not statistically different from that for patients who had a previous procedure. Having >1 previous operation did not significantly affect mortality. The length of hospital stay for hospital survivors ranged from 7 to 86 days (mean 21). This was no different than that for other patients of all ages during this time period.

Follow-up was obtained on 61 of 64 (95%) surviving

TABLE I Types of Anomalies in 77 Adult Patients Undergoing the Fontan Operation

NYHA = New York Heart Association.

patients 5 months to 12 years after operation (mean 4 years) (Table III). Three patients were lost to follow-up at 3.3, 3.6 and 5.3 years after operation. Complaints of heart rhythm disorder were followed up with inquiries to the patient's local physician when the rhythm diagnosis was unknown. Fifteen patients had a supraventricular tachyarrhythmia or atrial flutter of varying cycle lengths. Five patients had a complaint of occasional or frequent palpitations caused by premature ventricular beats. Two patients had bradyarrhythmia with atrioventricular dissociation. The occurrence of arrhythmias after the Fontan operation has been the subject of a previous report. Four patients had a permanent pacemaker, and 3 patients complained of varicose veins (2 men and 1 woman). Seventeen patients (27%) had intermittent ascites or edema early postoperatively but, with the passage of time and, in some instances, diuretic and dietary intervention, this became less of a problem in most.

Discussion

Previous studies have examined the effect of younger age, usually younger than 5 years, on the outcome of the Fontan procedure. These studies suggest that mortality is higher for the younger age group than for older children. Our experience also suggests an increased mortality in the younger age group. However, factors that necessitate operation at an early age seem to affect these results adversely. Many of the younger patients referred to our institution for Fontan repair are severely symptomatic secondary to deteriorating ventricular performance from volume overload produced by large pulmonary blood flow or atrioventricular valve incompetence. The higher mortality rate for these patients is probably a result of persistent myocardial dysfunction rather than of the Fontan repair itself.

For the adult patient with a single ventricle anomaly, the grim predictions regarding longevity made at the time of birth in the 1960s or earlier have not been realized. Many of these patients were told in their early years that nothing beyond palliation by shunts or banding would be available. Some of these patients have become productive wage earners, living well-adjusted, although perhaps sedentary, lives. The older patient who is reasonably well compensated and has become somewhat more independent in his or her lifestyle may be reluctant to consider a major surgical procedure in which the outcome is uncertain.

We present the early results of the Fontan operation in this group of patients to aid in the difficult decision of whether to consider a more definitive type of operation in these patients. Our goal in performing the Fontan procedure is to effectively reduce the ventricular volume load and to correct the arterial hypoxemia. It is hoped that this will prevent the myocardial deterioration and death in early adulthood that have characterized the natural history of these patients in the past and that the operation will increase longevity, with a reasonable and improved lifestyle. Whether the Fontan procedure will achieve these goals remains to be determined.

The hospital mortality in our group of patients was 6%. This percentage is significantly lower than that for patients younger than 18 years. Since 1980, there has been only 1 hospital death in 51 cases (2%). This rate compares favorably with a declining mortality rate for the entire group of patients undergoing the Fontan operation (10% overall, 6% tricuspid atresia, 12% double-inlet ventricle) for the same time—the more recent 5-year period. Better patient selection has been a positive influencing factor on the declining mortality rate, in addition to improved operative and postoperative management.

Arrhythmias, particularly supraventricular, may represent a significant late complication after the Fontan operation. Fifteen patients (24% of those followed up) had persistent supraventricular tachyarrhythmias. We have found that these rhythms are usually classic atrial flutter or other forms of paroxysmal atrial tachycardia. Atrioventricular block of 2:1 often occurs with these rhythms. After conversion to sinus rhythm, the initial therapy is usually digoxin and a type I antiarrhythmic agent (procainamide).

The long-term effect of elevated venous pressure on liver and gastrointestinal function, as well as on systemic veins, is unknown. Three patients complained of varicose veins in the lower extremities. This has not been a complaint of younger patients. However, the presence of this complaint may represent the combined effects of age and elevated systemic venous pressure. Despite 1 death from primary liver failure in this series, the occurrence of hepatic dysfunction is uncommon in our experience. In our series, 17 (27%) patients complained of intermittent ascites or edema, and this is a concern. Patients reported subjective improvement despite this complaint, and in most patients, this problem was well controlled by diet or diuretic medication and became less problematic with the passage of time. This seems to be a frequent complaint after the operation, and further investigation into the cause and treatment is needed.

Follow-up data suggest that most patients are doing well. The lack of need for medication and the subjective reports of improvement are encouraging. We continue to recommend that definitive exercise testing be performed on all patients who undergo the Fontan operation so that objective measures of improved performance may be recorded. A previous report from our institution has shown improved exercise tolerance after this operation.[6] As yet, too few adult patients have undergone this testing to report significant results.

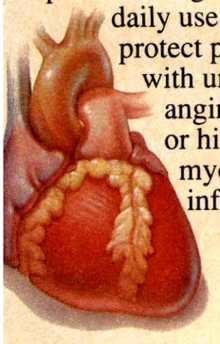
Ecotrin®. Recommended by cardiologists over Bayer® aspirin.

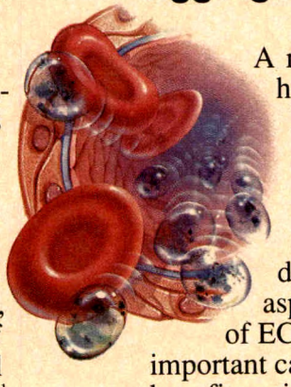
Aspirin therapy recommended by cardiologists.

ECOTRIN *is* aspirin–and it's the brand recommended by cardiologists more often than Bayer* aspirin for long-term daily use, to protect patients with unstable angina, TIA, or history of myocardial infarction.[1]



*Bayer® is a registered trademark of the Bayer Company.

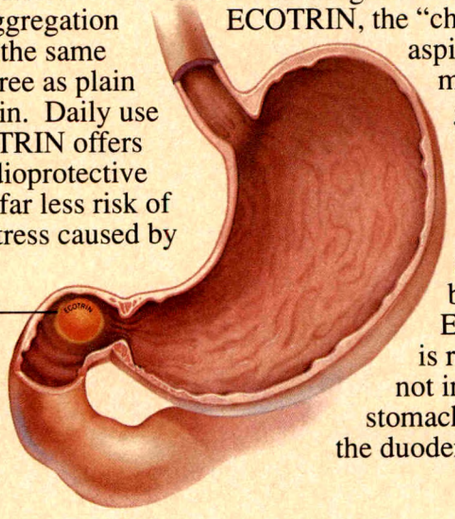
Effectively inhibits platelet aggregation.



A recent study[2] has shown that ECOTRIN inhibits platelet aggregation to the same degree as plain aspirin. Daily use of ECOTRIN offers important cardioprotective benefits–with far less risk of the gastric distress caused by plain aspirin.

Enteric-coated to spare the stomach.

More than 1,000 endoscopies have proved ECOTRIN superior to plain, buffered, and highly buffered aspirin in protecting the stomach in a regimen of 4 g a day.[3] ECOTRIN, the "chronic-use" aspirin, minimizes the gastric damage often associated with other forms of aspirin because ECOTRIN is released not in the stomach but in the duodenum.



ECOTRIN is released not in the stomach but in the duodenum.

Targeted-Release

Ecotrin®

Safety-Coated Aspirin 325 mg and 500 mg Tablets

The cardioprotective stomach-sparing aspirin.

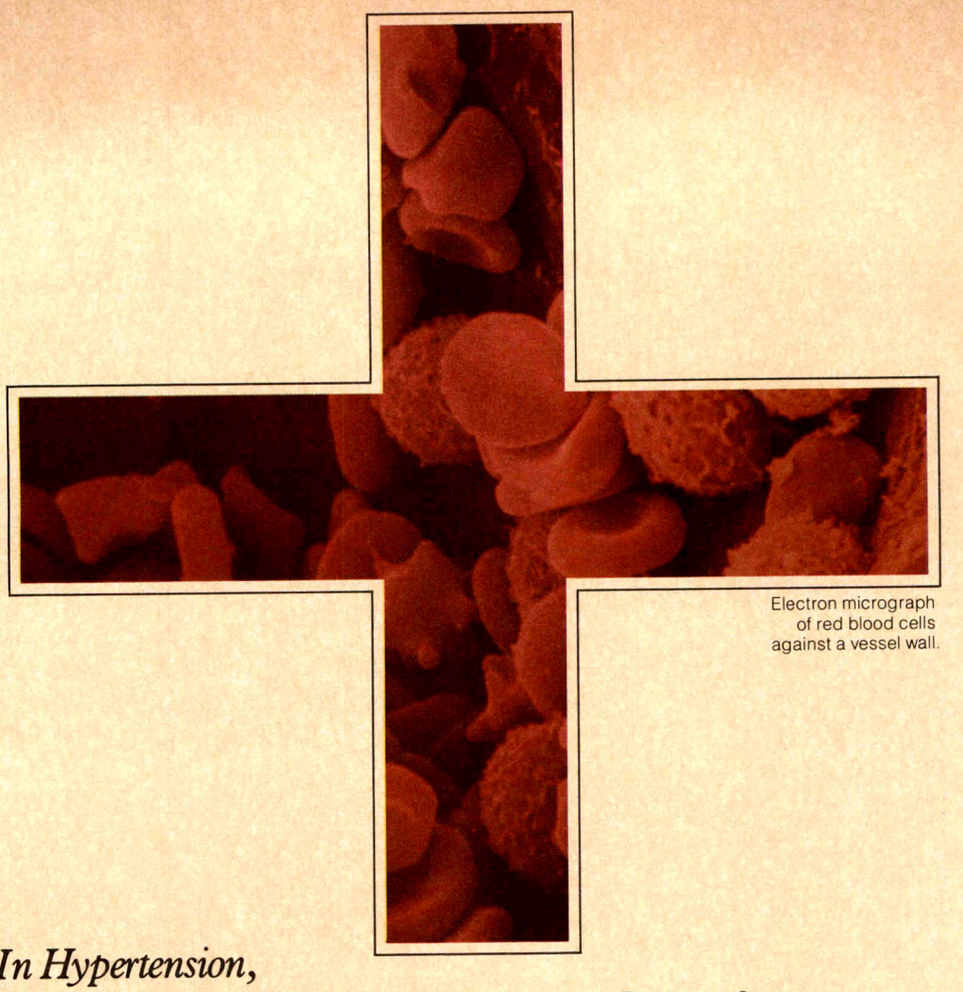
Electron micrograph of LDL molecules on cell surface

When you consider Coronary Heart Disease (CHD) risk reduction,

The lipid effects of thiazide diuretics may negate their positive antihypertensive effect.



Electron micrograph of red blood cells against a vessel wall.

In Hypertension,

Initiate Positive Action with Minipress®

(prazosin HCl)

First-line control of hypertension without the negatives of diuretics

Minipress and diuretics both deliver effective first-line blood pressure control. But unlike thiazide diuretics, Minipress does not compromise lipid metabolism[1-4]; additionally, potassium balance[5] and diabetes control are not compromised.[6,7] And sexual dysfunction is seldom a problem with Minipress.[8] Impotence has been reported but in less than 1% of patients on Minipress.

With Minipress, most common adverse reactions, generally mild and transient, are: dizziness, headache, drowsiness, palpitations, and nausea. Syncope has been reported in about 0.15% of patients at the recommended 1 mg initial dose. Fluid retention may occur.

Minipress.
The positive first-line approach to hypertension.
Instead of diuretics.

	Minipress	Thiazide Diuretics

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

Please see MINIPRESS® (prazosin HCl) brief summary on adjacent page.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

Brief Summary
MINIPRESS (prazosin hydrochloride) CAPSULES ***For Oral Use***

INDICATIONS AND USAGE: MINIPRESS (prazosin hydrochloride) is indicated in the treatment of hypertension. It is mild to moderate in activity and can be used as the initial agent or in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed.

CONTRAINDICATIONS: None known.

WARNINGS: MINIPRESS may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120–160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS. The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS therapy.

PRECAUTIONS: ***Information for Patients:*** Dizziness or drowsiness may occur after the first dose of this medicine. Avoid driving or performing hazardous tasks for the first 24 hours after taking this medicine or when the dose is increased. Dizziness, lightheadedness or fainting may occur, especially when rising from a lying or sitting position. Getting up slowly may help lessen the problem. These effects may also occur if you drink alcohol, stand for long periods of time, exercise, or if the weather is hot. While taking MINIPRESS, be careful in the amount of alcohol you drink. Also, use extra care during exercise or hot weather, or if standing for long periods. Check with your physician if you have any questions.

Drug Interactions: MINIPRESS has been administered without any adverse drug interaction in limited clinical experience to date with the following: (1) cardiac glycosides–digitalis and digoxin; (2) hypoglycemics–insulin, chlorpropamide, phenformin, tolazamide, and tolbutamide; (3) tranquilizers and sedatives–chlordiazepoxide, diazepam, and phenobarbital; (4) antigout–allopurinol, colchicine, and probenecid; (5) antiarrhythmics–procainamide, propranolol (see WARNINGS however), and quinidine; and (6) analgesics, antipyretics and anti-inflammatories–propoxyphene, aspirin, indomethacin, and phenylbutazone.

Addition of a diuretic or other antihypertensive agent to MINIPRESS has been shown to cause an additive hypotensive effect.

Drug/Laboratory Test Interactions: False positive results may occur in screening tests for pheochromocytoma in patients who are being treated with prazosin. If an elevated VMA is found, prazosin should be discontinued and the patient retested after a month.

Laboratory Tests: In clinical studies in which lipid profiles were followed, there were generally no adverse changes noted between pre- and post-treatment lipid levels.

Carcinogenesis, Mutagenesis, Impairment of Fertility: No carcinogenic potential was demonstrated in an 18 month study in rats with MINIPRESS (prazosin hydrochloride) at dose levels more than 225 times the usual maximum recommended human dose of 20 mg per day. MINIPRESS was not mutagenic in *in vivo* genetic toxicology studies. In a fertility and general reproductive performance study in rats, both males and females, treated with 75 mg/kg (225 times the usual maximum recommended human dose), demonstrated decreased fertility while those treated with 25 mg/kg (75 times the usual maximum recommended human dose) did not.

In chronic studies (one year or more) of MINIPRESS in rats and dogs, testicular changes consisting of atrophy and necrosis occurred at 25 mg/kg/day (75 times the usual maximum recommended human dose). No testicular changes were seen in rats or dogs at 10 mg/kg/day (30 times the usual maximum recommended human dose). In view of the testicular changes observed in animals, 105 patients on long term MINIPRESS therapy were monitored for 17-ketosteroid excretion and no changes indicating a drug effect were observed. In addition, 27 males on MINIPRESS for up to 51 months did not have changes in sperm morphology suggestive of drug effect.

Usage In Pregnancy: Pregnancy Category C. There are no adequate and well controlled studies which establish the safety of MINIPRESS (prazosin HCl) in pregnant women. MINIPRESS should be used during pregnancy only if the potential benefit justifies the potential risk to the mother and fetus.

Nursing Mothers: MINIPRESS has been shown to be excreted in small amounts in human milk. Caution should be exercised when MINIPRESS is administered to a nursing woman.

Usage in Children: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Clinical trials were conducted on more than 900 patients. During these trials and subsequent marketing experience, the most frequent reactions associated with MINIPRESS therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

Less frequent adverse reactions which are reported to occur in 1–4% of patients are:

Gastrointestinal: vomiting, diarrhea, constipation; *Cardiovascular:* edema, orthostatic hypotension, dyspnea, syncope; *Central Nervous System:* vertigo, depression, nervousness; *Dermatologic:* rash; *Genitourinary:* urinary frequency; *EENT:* blurred vision, reddened sclera, epistaxis, dry mouth, nasal congestion.

In addition, fewer than 1% of patients have reported the following (in some instances, exact causal relationships have not been established):

Gastrointestinal: abdominal discomfort and/or pain, liver function abnormalities, pancreatitis; *Cardiovascular:* tachycardia; *Central Nervous System:* paresthesia, hallucinations; *Dermatologic:* pruritus, alopecia, lichen planus; *Genitourinary:* incontinence, impotence, priapism; *EENT:* tinnitus; *Other:* diaphoresis, fever.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported.

OVERDOSAGE: Should overdosage lead to hypotension, support of the cardiovascular system is of first importance. Restoration of blood pressure and normalization of heart rate may be accomplished by keeping the patient in the supine position. If this measure is inadequate, shock should first be treated with volume expanders. If necessary, vasopressors should then be used. Renal function should be monitored and supported as needed. Laboratory data indicate MINIPRESS is not dialysable because it is protein bound.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS should be adjusted according to individual blood pressure response.

Initial Dose: 1 mg two or three times a day.

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

The Heart and Hypertension

Franz H. Messerli, MD, Editor

"Like the kidney and the brain, the heart plays a three-fold role in essential hypertension: first, it is directly involved in the pathogenesis of arterial hypertension. ... Second, the heart suffers as a target organ of long-standing hypertension.... Third, cardiac function and structure are directly and indirectly affected by a variety of antihypertensive agents.

[This] book is written for physicians, cardiologists, or investigators who would like to deepen their understanding of cardiac involvement in hypertension, and of progression as well as regression of left ventricular hypertrophy, and the heart's structural and functional response to various blood pressure lowering agents."

—from the Editor's Preface

The Heart and Hypertension features contributions from 88 internationally recognized experts. *The Heart and Hypertension:* 482 pages—including a subject index—in 45 chapters.

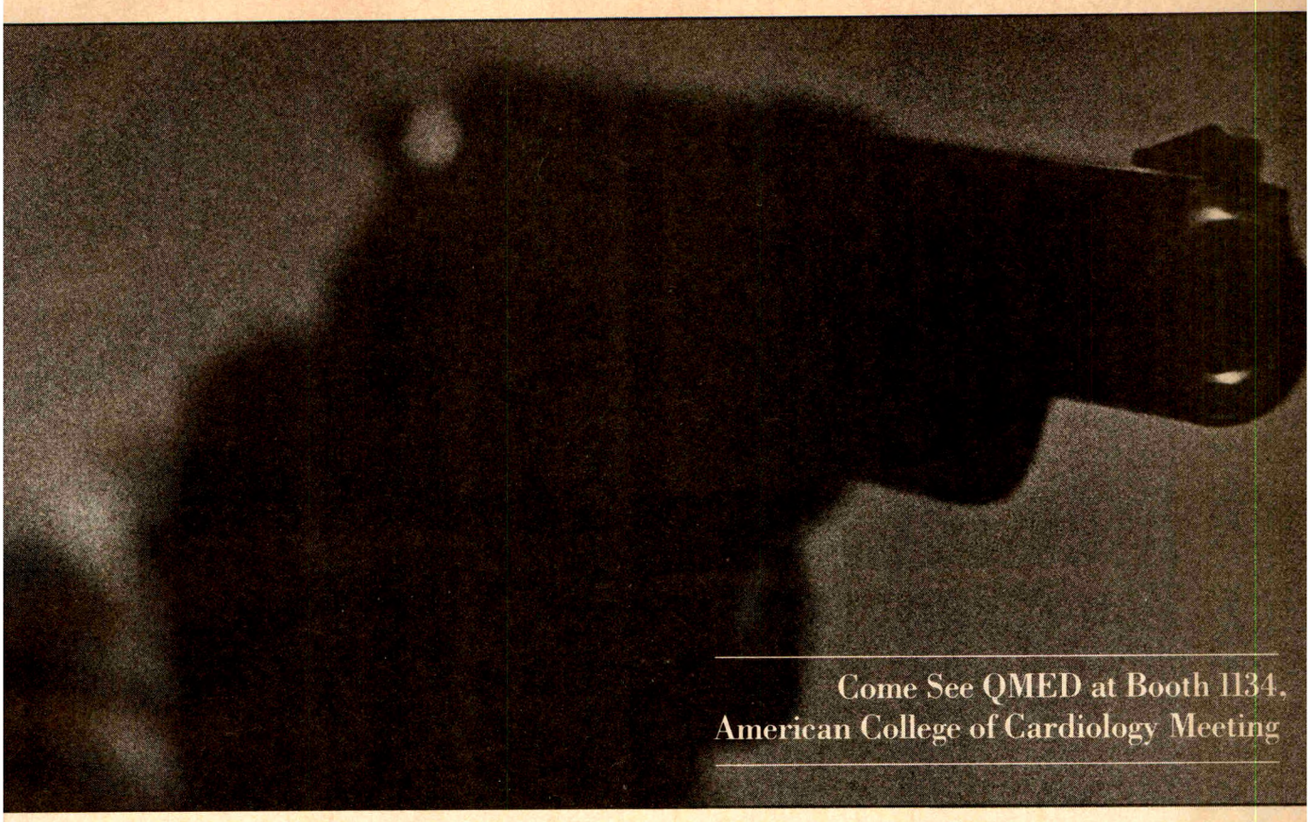
ISSUES IN ISCHEMIA



Ischemia kills more people in one day than handguns kill in a year

This year, nearly 1,000 people will be killed by handguns.[1]* But in the *next day alone*, over 1,000 people will be killed by ischemic heart disease. Tomorrow, another 1,000. And by the time the year is out, over one-half million lives will have been taken by the disease.[2]

Is there anything you can do to prevent this?

Yes. You can monitor patients for ischemia. Because detection of the disease is the necessary first step in treating it.

For too long now, physicians have had to rely on a single day of Holter monitoring to uncover ischemia. But because of the day-to-day variability of the disease, a single day of monitoring is simply inadequate. A recent study has now determined that you must monitor for no less than 48 hours to ensure an accurate assessment of the severity of ischemia.[3]

That is why, for optimal management of ischemia, physicians need to assess the ongoing cardiac condition with a *multi-day* cardiac monitor.

A monitor that can be worn comfortably by a patient for up to eight days, virtually artifact-free. A monitor that can produce thorough, understandable cardiac reporting in a matter of minutes, without tapes, technicians, or an expensive base station. A monitor that is clinically validated for detecting ST depression—100% sensitive and 92% specific.†

Q-Med knows what is needed for optimal management of ischemia because Q-Med has engineered the optimal ischemia monitor—Monitor One TC™. . . now in two channels.

If you are serious about confronting ischemia, think about this: In the minute it takes you to read this page, someone will die from ischemia. Shouldn't you be using the best technology available to manage it?

No longer will increasing your ad budget be an act of faith.

About $3 billion a year is spent on business press advertising–yet amazingly little concrete evidence has existed to show whether it really works.

Research to actually prove the effectiveness of trade and industrial advertising has been unconvincing and inconclusive.

Till now.

Finally. New research proves business press advertising dramatically increases sales and profits.

It's comprehensive. This landmark research study took more than three years to complete at a cost of over $390,000.

It's impartial–the study was conducted entirely by the independent Advertising Research Foundation.

It's reliable. The new study tracked ads for four totally different products. Was based on real-time data carefully accumulated as the ads ran. And employed state-of-the-art data analysis techniques.

It's conclusive. It links higher levels of advertising with significant increases in sales, plus increased profits. Considering the competitive crunch of today's marketplace, these kinds of results mean increasing your advertising is no longer an act of faith–but an act of survival.

Shoot down your old notions, and put the research to work.

Armed with these new, easy-to-understand facts and figures, you can now have powerful decision support for increasing your trade magazine ad budget.

For your copy of the "Summary of the Findings", write on your letterhead to: Marketing Services, Association of Business Publishers, 205 E. 42nd Street, New York, NY 10017.

ABP

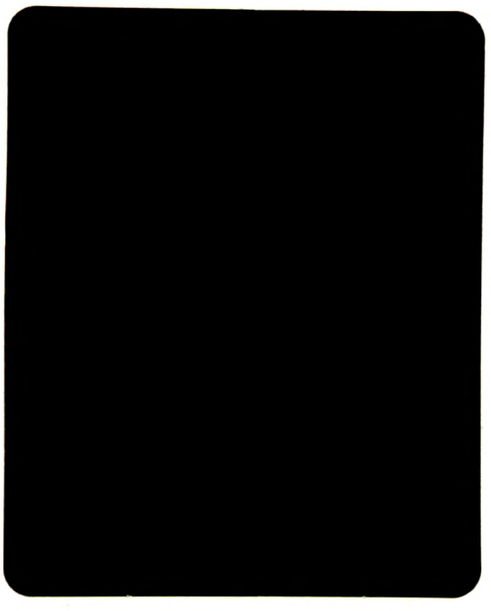
A proven part of your sales force.

There's a logical choice for mild-to-moderate pain relief in patients on MI/TIA aspirin therapy.
It's not more aspirin.

Analysic doses of aspirin can result in therapeutic noncompliance.

GI side effects can increase when MI/TIA patients on low-dose aspirin use more aspirin for pain relief.

You know how important it is for your MI/TIA patients to adhere to a prescribed regimen of daily low-dose aspirin. Recent long-term studies on aspirin therapy for prevention of stroke or MI indicate that one regular-strength aspirin per day provides comparable antiplatelet effects to approximately four aspirin tablets per day but with reduced risk of GI side effects.[1-4]



But what might happen when your MI/TIA patient uses additional aspirin for pain relief when he or she has a headache or a cold or flu? Prophylactic therapy for MI/TIA may be compromised by the increased risk of GI side effects when your patient takes additional aspirin for other reasons.

Studies have shown that even routine doses of aspirin can cause GI side effects. Aspirin-associated dyspepsia has been estimated to occur in 5% to 25% of all aspirin users. And endoscopic studies in healthy volunteers demonstrate that analgesic doses of aspirin can result in GI erosions, ulcerations, and submucosal hemorrhage.[5-7]

Extra-Strength TYLENOL® acetaminophen: The right choice for mild-to-moderate pain relief.

For patients on low-dose aspirin therapy, Extra-Strength TYLENOL® is the ideal analgesic for mild-to-moderate pain.

EXTRA-STRENGTH
TYLENOL®
500 mg acetaminophen

First choice for mild-to-moderate pain relief in patients on low-dose aspirin therapy

Effective pain relief...

Clinical studies have demonstrated the superior efficacy of Extra-Strength TYLENOL® (1000 mg) for mild-to-moderate pain when compared to regular-strength aspirin (650 mg), and equal efficacy, mg for mg, to 1000 mg aspirin.[8,9] What's more, in a recent major headache study, Extra-Strength TYLENOL® was shown equal in efficacy to OTC ibuprofen (200 mg and 400 mg).[10]

with little risk of GI irritation...

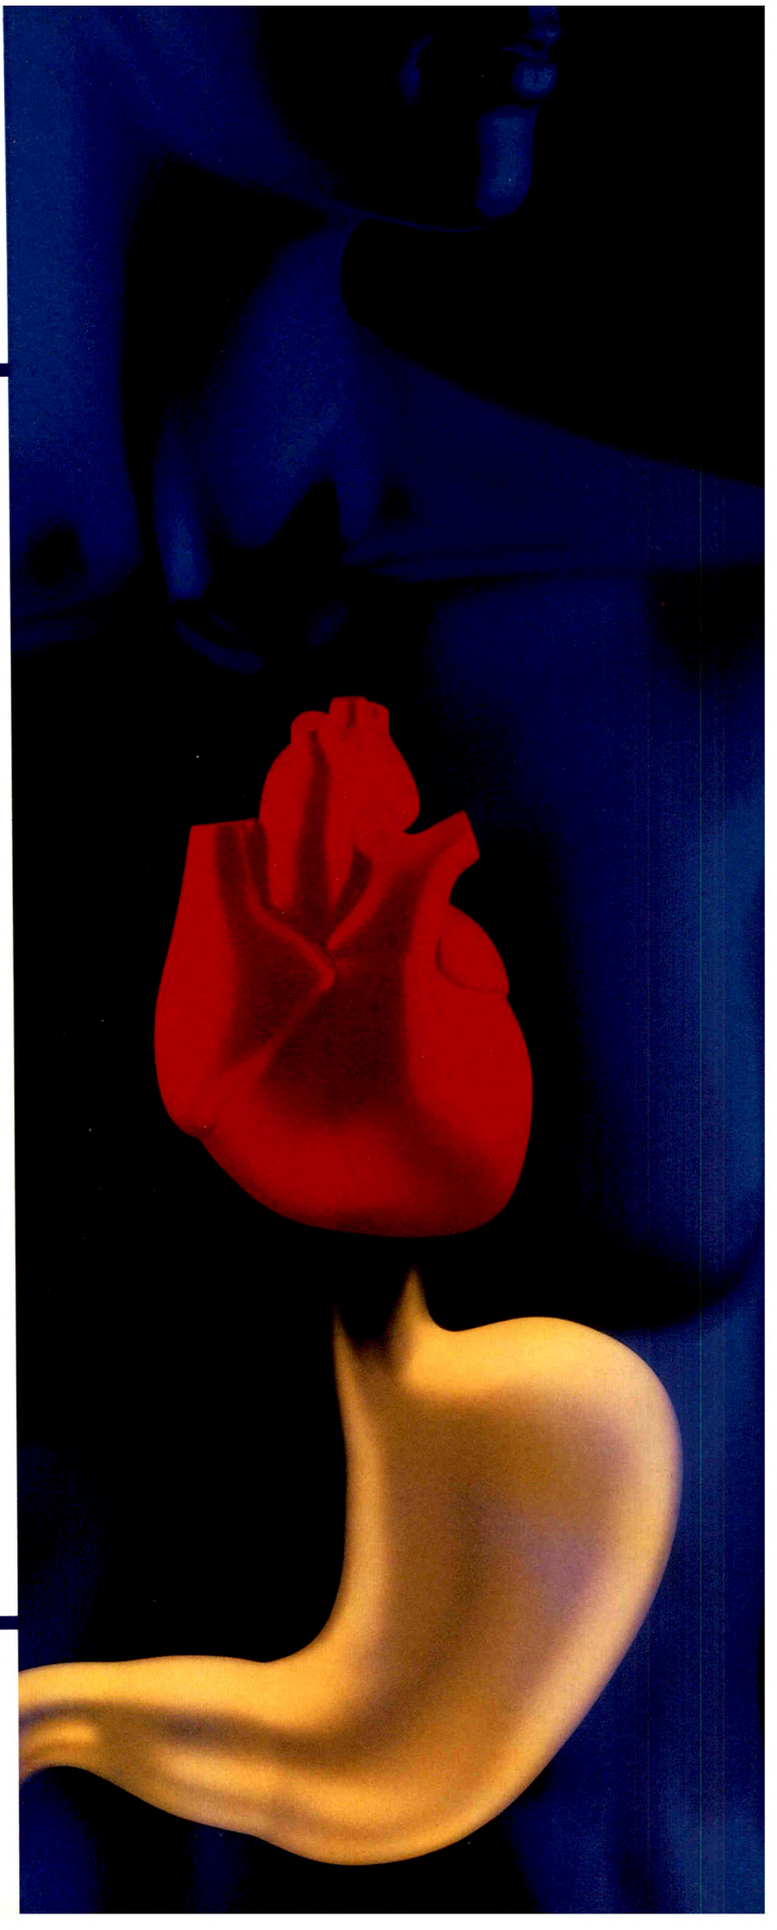
Although to a lesser degree than aspirin, even OTC ibuprofen can cause erosions, ulcerations, and submucosal hemorrhage.

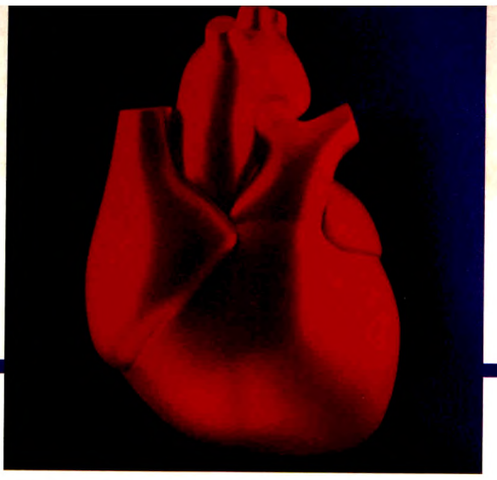
With Extra-Strength TYLENOL®, there is little likelihood of this type of GI irritation.[11,12] By minimizing the risk of GI irritation, your patient's compliance is less likely to be jeopardized.

that won't interfere with the antiplatelet effects of low-dose aspirin therapy.

Another important consideration for MI/TIA patients: Extra-Strength TYLENOL® won't influence the desired antiplatelet effects of low-dose aspirin, so antiplatelet therapy won't be affected.[12,13]

Reduce the risk of compromised therapy due to simple analgesia. When you recommend low-dose aspirin for MI/TIA patients, you may wish to advise them against taking additional aspirin for simple pain relief. Specify the logical choice: Extra-Strength TYLENOL®.





Why risk compromising therapy for the sake of simple analgesia?

Keep low-dose aspirin at low doses for MI/TIA therapy

For mild-to-moderate pain relief:

EXTRA-STRENGTH TYLENOL®

500 mg acetaminophen

- No OTC analgesic is more effective for mild-to-moderate pain
- Little risk of GI irritation
- Does not interfere with antiplatelet effects

First choice for mild-to-moderate pain relief in patients on low-dose aspirin therapy

Effect of Iron Deficiency on Tissue Oxygen Delivery in Cyanotic Congenital Heart Disease

SAMUEL S. GIDDING, MD, and JAMES A. STOCKMAN III, MD

To test the hypothesis that tissue oxygen delivery would be affected by diminished oxygen stores in cyanotic congenital heart disease, serum ferritin, transferrin saturation, hemoglobin, red cell mean corpuscular volume (MCV), red cell 2,3-diphosphoglycerate (DPG), P50, blood gases, oxygen saturations and systemic oxygen transport were measured in 29 hypoxemic infants and children. For the group, aortic saturation was 81 ± 9%, PaO_2 was 50 ± 12 mm Hg, hemoglobin 16.2 ± 2.1 gm/dl and systemic oxygen transport 620 ± 145 ml/min/m^2. P50 was increased above normal values (28.8 ± 2.3 vs 26.6 ± 1.1 mm Hg, p <0.01), and DPG was 2.35 ± 0.54 μmol/ml, at the upper limits of normal for this assay. Iron deficiency was present in 8. When patients with P50 ≥30 mm Hg and P50 <30 mm Hg were compared, iron stores were diminished in the high P50 group: [serum ferritin (19 ± 8 vs 53 ± 48 ng/ml, p = 0.0006), transferrin saturation (11 ± 6 vs 23 ± 11%, p = 0.003) and MCV (79 ± 8 vs 86 ± 4 fl, p = 0.05)]. Hemoglobin, aortic oxygen saturation, PaO_2 and systemic oxygen transport were similar in both groups. In children with iron sufficiency, 15 of 21 had MCV >90th percentile for age and sex (p <0.001 versus expected distribution). Also, MCV >90th percentile for age and sex had a positive predictive value of 0.88 for iron sufficiency. This study demonstrates that diminished iron stores in cyanotic congenital heart disease are associated with a more right-shifted oxyhemoglobin dissociation curve (increased P50). In addition, MCV was larger than in normal patients and, if >90th percentile for age and sex, suggested iron sufficiency.

(Am J Cardiol 1988;61:605–607)

An important goal in the management of cyanotic congenital heart disease is to provide adequate tissue oxygen delivery despite chronic hypoxemia. Many cyanotic patients are managed by palliative surgical and catheterization procedures that raise systemic arterial oxygen tension so that physiologic compensation through polycythemia and rightward shifting of the oxyhemoglobin dissociation curve can occur.[1-3] Recent studies have shown that patients with cyanotic congenital heart disease alter their cardiac index, hemoglobin concentration and oxyhemoglobin dissociation curve to maintain a level of systemic oxygen transport similar to that of acyanotic patients.[4]

From the Division of Cardiology, The Children's Memorial Hospital, Department of Pediatrics, Northwestern University Medical School, Chicago, Illinois. This study was supported in part by the Robert and Mary Wood Research Fellowship Grant. Manuscript received July 2, 1987; revised manuscript received and accepted October 26, 1987.

Address for reprints: Samuel S. Gidding, MD, Division of Cardiology, Children's Memorial Hospital, 2300 Children's Plaza, Chicago, Illinois 60201.

We hypothesized that tissue oxygen delivery would be adversely affected by decreased iron stores in cyanotic congenital heart disease because of an adverse effect on hemoglobin production.[5] Tissue oxygen delivery was defined as abnormal if the oxyhemoglobin dissociation curve was right-shifted in the presence of normal cardiac index, pH and temperature. To test this hypothesis we assessed tissue oxygen delivery and iron storage variables in 29 children undergoing cardiac catheterization.

Methods

Infants and children undergoing elective cardiac catheterization for cyanotic congenital heart disease were studied. Specifically excluded from the protocol were critically ill children, those <3 months of age, or with Down syndrome, which is associated with increased red cell mean corpuscular volume (MCV).[6] All parents gave consent for the study according to an institutionally approved form.

Hemoglobin and MCV were measured before cardiac catheterization (Coulter counter). At catheterization, blood was drawn for arterial blood gases (Radiometer Copenhagen ABL 30), measured aortic and

TABLE I Laboratory Data for All Patients

	Mean ± SD	Range
Aortic saturation (%)	81 ± 9	50–91
PaO_2 (mm Hg)	50 ± 12	30–70
Hemoglobin (g/dl)	16.2 ± 2.1	12.2–22.1
MCV (fl)	85 ± 6	64–98
Ferritin (ng/ml)	44 ± 43	5–175
Transferrin saturation (%)	19 ± 11	4–48
Systemic O_2 transport (ml/min/m^2)	620 ± 145	375–1018
P50 (mm Hg)	28.8 ± 2.3	25.5–33.9
Red cell 2,3-DPG (μmol/ml)	2.35 ± 0.54	1.58–4.17

DPG = diphosphoglycerate; MCV = mean corpuscular volume; SD = standard deviation.

TABLE II Iron Storage Variables

Variable	P50 ≥30 mm Hg	P50 <30 mm Hg	p Value
Ferritin (ng/ml)	19 ± 8	53 ± 48	0.006
Transferrin saturation (%)	11 ± 6	23 ± 11	0.003
MCV (fl)	79 ± 8	86 ± 4	0.05
Hemoglobin (g/dl)	16.5 ± 2.1	16.3 ± 2.1	0.84

MCV = mean corpuscular volume.

TABLE III Oxygen Delivery Variables

Variable	P50 ≥30 mm Hg	P50 <30 mm Hg	p Value
Aortic saturation (%)	75 ± 13	83 ± 7	0.15
PaO_2 (mm Hg)	45 ± 13	52 ± 12	0.19
Systemic O_2 transport (ml/min/m^2)	613 ± 101	623 ± 169	0.87
Red cell 2,3-DPG (μmol/ml)	2.76 ± 0.74	2.17 ± 0.31	0.07

DPG = diphosphoglycerate.

mixed venous oxygen saturations (American Optical Unistat Oximeter), P50 (Hemoxanalyzer), red blood cell 2,3-diphosphoglycerate (DPG) (Sigma Diagnostics Kit), fetal hemoglobin, serum ferritin, serum iron and total iron binding capacity. Oxygen consumption was measured using a flow-through hood (Waters Instruments, MRM-2) in 22 children.

Calculated variables included transferrin saturation; oxygen carrying capacity; cardiac index (Fick principle); systemic oxygen transport (arterial O_2 content × cardiac index); P50 in vivo, which was calculated using measured pH and a mathematical description of the Bohr effect ($\Delta \log P50 = -0.37\ [\Delta pH]$);[7] and DPG corrected for fetal hemoglobin concentration ([DPG, observed] × [100 − % hemoglobin F] = DPG functional).[8] Values of P50 and DPG reported were corrected for pH and hemoglobin F concentration by the above equations. Iron deficiency was defined as present if 1 or more of the following were noted: serum ferritin ≤12 ng/ml, transferrin saturation ≤7% in children <2 years of age or ≤16% in children >2 years of age, red cell MCV ≤5th percentile for age and sex in the absence of thalassemia syndrome or serum iron <50 mg/dl if total iron binding capacity was not available.[9]

Statistical analysis: Means and standard deviations were performed on all variables for the group as a whole. Patients were then divided into 2 groups: those with right-shifted oxyhemoglobin dissociation curves (P50 ≥30 torr) and those with lower P50 values. Groups were compared using an unpaired *t* test, with $p < 0.05$ for a 2-tailed test considered statistically significant. Data are presented as mean ± standard deviation.

To assess the reliability of MCV as a predictor of iron sufficiency, MCV was expressed as a percentile for age and sex.[10] The distribution of MCV in the iron-sufficient population was compared with the expected normal distribution in the population by chi-square analysis. The sensitivity, specificity and predictive value of MCV criteria for iron sufficiency for the study population were calculated.

Results

Twenty-nine patients (18 boys, 11 girls) were enrolled in the study. Mean age was 2.9 ± 2.3 years and mean weight was 13.6 ± 9.1 kg. Diagnoses included complete transposition in 9, tetralogy of Fallot in 9, other forms of right ventricular outflow tract obstruction in 5 and complex anomalies in 6.

Baseline study variables for the group as a whole are presented in Table I. The patients had significant hypoxemia and polycythemia. Of the 29 patients, 26 had hemoglobin concentration >97th percentile for age and sex, 2 were between the 90th and 97th percentiles and 1 was 50th percentile.[9] MCV was increased above normal values reported for age and sex. The oxyhemoglobin dissociation curve was right-shifted as demonstrated by increased values for P50 (28.8 ± 2.3 vs 26.6 ± 1.1 mm Hg, $p < 0.01$ vs normal values for our laboratory). Iron deficiency was diagnosed in 8 patients: low serum ferritin in 3, low transferrin saturation in 3, low transferrin saturation and low MCV in 1, and low serum ferritin, transferrin saturation and MCV in 1.

Tables II and III compare iron storage oxygen delivery variables after patients had been subdivided according to the degree of the rightward shift in the oxyhemoglobin dissociation curve. Age was similar in these groups (2.9 ± 1.8 years, P50 ≥30 mm Hg vs 3.7 ± 3.2 years, P50 <30 mm Hg). Although hemoglobin concentration was similar in both groups, children with elevated P50 had significantly lower serum ferritin, transferrin saturation and MCV. The difference in DPG approached (but did not achieve) a statistical difference. Neither aortic saturation nor PaO_2 were statistically different.

An interesting finding was an unusual distribution of MCV in our study population. In iron-sufficient children, MCV was >90th percentile for age and sex in 15 of 21 ($p < 0.001$ vs expected distribution), whereas only 2 of 8 iron-deficient children had MCV >90th percentile. The presence of an MCV >90th percentile was a good test of iron sufficiency (positive predictive value = 0.88), but its absence did not necessarily indicate iron deficiency (negative predictive value = 0.50).

An MCV <3rd percentile for age and sex was found in 2 patients in our series, 1 had a low serum ferritin and the other a low transferrin saturation. Patients treated for iron deficiency in this series had increases in MCV >90th percentile for age and sex.

Discussion

The principal finding was that diminished iron stores affected tissue O_2 delivery in cyanotic congenital heart disease. A significantly right-shift oxyhemoglobin dissociation curve in our patient population represented physiologic compensation for both chronic hypoxemia and relative anemia. The presence of P50 >30 mm Hg in a patient with chronic hypoxemia suggested the possible presence of iron deficiency, even if the patient had mild to moderate polycythemia.

Our study identified a useful marker for iron sufficiency (MCV >90th percentile for age and sex). Although not as specific as serum ferritin, this measurement is useful in confirming the presence of iron sufficiency. If the MCV is <90th percentile for age and sex, further assessment of iron stores is appropriate. In our experience, which also encompasses patients not included in this study, an MCV <3rd percentile for age and sex has been uniformly associated with severe iron deficiency or thalassemia syndrome.

We do not have a good explanation for the elevation of MCV in hypoxemic patients. MCV is known to be elevated in newborn infants, patients with folate or B_{12} deficiency, Down syndrome, hypothyroidism, liver disease, reticulocytosis and chronic obstructive pulmonary disease.[10] Oldag et al[11] noted this phenomenon in cyanotic congenital heart disease and concluded that neither an increased number of reticulocytes nor a shorted red cell survival were responsible for the increase in red cell size. It seems unlikely that either folate or B_{12} deficiency existed in our study population.[12] Another hypothesis to consider is a resumption of fetal forms of erythropoiesis, although fetal hemoglobin concentrations were within normal limits with the exception of 1 patient who was born prematurely.

The clinical importance of iron deficiency in cyanotic congenital heart disease has been emphasized in several studies. Cerebrovascular accidents in younger cyanotic children occur much more commonly in the setting of relative anemia than with severe polycythemia.[13,14] Linderkamp et al[15] showed that iron-deficient cells are less deformable and actually increase blood viscosity despite the presence of a lower hemoglobin concentration. In recent assessments of serum erythropoietin titer in patients with cyanotic congenital heart disease, several patients with low serum ferritin concentrations were identified and shown to have a tendency toward elevated erythropoietin titers suggestive of relative anemia.[16,17]

Berman et al[4] studied systemic oxygen transport in a large cohort of patients with congenital heart disease. These investigators concluded that P50, DPG and hemoglobin concentration fluctuate to stabilize arterial oxygen content. Cardiac index is then the major determinant of systemic oxygen transport. Our data would support this conclusion because systemic oxygen transport was similar among the higher and lower P50 groups. If we consider that hypoxemic iron-deficient patients may have lower hemoglobin concentrations than are appropriate and that compensatory mechanisms work to normalize systemic oxygen transport, the cost of iron deficiency may include increased resting cardiac index, right shifted oxyhemoglobin dissociation curve and lower mixed venous oxygen content.

Acknowledgment: We wish to thank Eric Valcourt for technical assistance and Shann Bulger for help in preparing the manuscript.

Surgical Risk Factors in Total Anomalous Pulmonary Venous Connection

CHRISTOPHER R. LINCOLN, FRCS, MICHAEL L. RIGBY, MD, CORRADO MERCANTI, MD, MOHAMMAD AL-FAGIH, FRCS, MICHAEL C. JOSEPH, MD, GRAHAM A. MILLER, MD, and ELLIOTT A. SHINEBOURNE, MD

Eighty-three patients underwent surgical correction of total anomalous pulmonary venous connection (TAPVC) between 1973 and 1986. There were 46 boys and 37 girls. Median age at operation was 60 days (1 to 240) and median weight 3.9 kg (1 to 22). The anatomic types encountered included infracardiac connection (16 patients), supracardiac connection (32) and pulmonary venous drainage connected directly to the coronary sinus (27). Mixed anomalous drainage or pulmonary venous return connected directly to the right atrium occurred in 8 patients. Diagnosis was established by cardiac catheterization and angiography (56 patients), clinical examination (3) and cross-sectional echocardiography alone in 24 of the last consecutive 28 patients. Pulmonary hypertension was present in 26 (55%) of those who underwent cardiac catheterization. The median pulmonary vascular resistance was 4.2 units/m^2 (body surface area) for all the patients, whereas in those with infracardiac pulmonary venous connection the median value was 10 units/m^2. The median interval between admission and operation was 72 hours. Surgical correction was performed using profound hypothermia and circulatory arrest in 68; for the remainder, conventional cardiopulmonary bypass with profound to moderate hypothermia was used. Ten patients developed 1 or more pulmonary hypertensive crises during the early postoperative period. These were diagnosed in 8 by direct pulmonary artery pressure measurement and in 2 by clinical examination. Late reoperation was necessary in 6 patients (10%). Analyses of risk factors for 30-day survival for all patients showed that the risk of early death was associated with the type of anomaly (infradiaphragmatic), occurrence of pulmonary hypertensive crises, year of the operation, sex of the patient and presence of preoperative congestive heart failure. The risk of early death was decreased when the method of diagnosis was cross-sectional echocardiography alone. The 30-day hospital mortality from 1975 to the present was 8.5%. Six patients (10%) died later than expected. Actuarial survival of patients with infradiaphragmatic drainage was 60% at 72 months and the remainder had an 88% survival at 80 months. The whole group had an actuarial survival of 75% at 84 months.

(Am J Cardiol 1988;61:608–611)

Successful surgical correction of total anomalous pulmonary venous connection (TAPVC) was first reported by Muller[1] in 1951. Before 1970, the surgical mortality for the correction of this anomaly was significantly higher in infancy. Some authors regarded young age as a major factor in determining mortality.[2] More recently, improved results have been reported in infancy, and young age at operation has not been considered a risk factor.[3–6] These authors generally agreed that any delay in effective surgical treatment of symptomatic infants gives rise to a higher operative mortality. They also noted that mortality was most closely related to the anatomical type of anomalous pulmonary venous return. In a recent study, multivariant analysis showed no significant association between early mortality and age or weight at operation, preoperative pulmonary or systemic pressure and the preoperative condition of patients undergoing surgery.[7]

We retrospectively reviewed 83 patients with isolated TAPVC treated consecutively at our institution between 1973 and 1986. Excluded were patients with atrial isomerism and any who did not have concordant atrioventricular and ventriculoarterial connections. This study seeks to identify the incremental risk factors for death in the total surgical treatment of TAPVC by 1 surgeon.

Patients: There were 46 boys and 37 girls. Thirty-one had supracardiac drainage, most to the left vertical vein, and one had a supracardiac connection directly to the right superior vena cava (group 1). Infradiaphragmatic drainage was present in 16 (group 2). The anomalous connection was to coronary sinus in 27 (group 3) and directly to the right atrium or mixed in the remaining 8 (group 4.)

TABLE I Clinical and Catheterization Data (n = 83)

	Group 1	Group 2	Group 3	Group 4
	Supracardiac (n = 32)	Infracardiac (n = 16)	Coronary Sinus (n = 27)	Mixed (n = 8)
Age at operation (days)	80 (1–180)	14 (1–42)	71 (3–240)	90 (2–120)
Weight (kg)	4 (3–13)	3 (1–4)	4 (2–22)	4 (3–7)
BSA (m^2)	0.26 (0.2–0.4)	0.20 (0.1–0.2)	0.25 (0.1–0.4)	0.25 (0.2–0.3)
Days in hospital before operation	2 (0–11)	1 (0–13)	3 (0–22)	5 (0–21)
pH on admission	7.35 (7.0–7.4)	7.30 (7.2–7.5)	7.35 (7.0–7.5)	7.39 (7.3–7.4)
PA systolic (mm Hg)	60 (18–130)	70 (41–100)	45 (24–114)	46 (20–76)
PVR (units m^2)	4.8 (1.0–9.0)	10 (2–20)	3.0 (3–20)	2.7 (1–3)
Qp/Qs	1.9 (0.8–7.4)	1.4 (0.6–1.9)	2.9 (1.8–4.0)	4.0 (1.0–11)
Hospital survival	30 (93%)	11 (68%)	24 (88%)	6 (75%)

All the above indexes are median with range.
BSA = body surface area; PA = pulmonary artery pressure; PVR = pulmonary vascular resistance; Qp/Qs = pulmonary to systemic blood flow.

The analysis was done using distribution-free methods (instead of more widely used normal-based methods), and the variables have been described in the text in terms of median value and range. The minimum value was usually close to the median.

Patient information at the time of hospital admission is listed in Table I.

In contrast to the whole and other groups, patients in group 2 were smaller and tended to be more critically ill at the time of admission. Median age at operation was 14 days (range 1 to 42), median weight 3 kg (range 1 to 4) and median body surface area 0.2 m^2 (range 0.1 to 0.2). The median for the total number of days spent at the referring hospital before admission to our unit was 1 day (range 0 to 13). Median pH on admission was 7.3 (range 7.2 to 7.5).

Cardiac catheterization and cross-sectional echocardiography (special investigation): Fifty-six patients underwent conventional cardiac catheterization and angiography to establish the diagnosis and to clarify the type of anomalous venous return. Twenty-four were diagnosed by cross-sectional echocardiography alone and 3 underwent surgery on the basis only of clinical examination and appearances of the chest radiograph. In those patients undergoing cardiac catheterization, cineangiography usually delineated the type of TAPVC. Measurements were made of the pulmonary artery systolic pressure, the pulmonary vascular resistance and the pulmonary to systemic flow ratio. Pulmonary vascular resistance was calculated using assumed values for oxygen consumption according to the data of Cayler and Rudolph.[8]

Patients in group 2 had a higher pulmonary artery pressure and greater pulmonary vascular resistance. The median for the pulmonary artery systolic pressure was 70 mm Hg (range 41 to 100) and the pulmonary vascular resistance had a median value of 10 units (range 2 to 48 units). The estimation of pulmonary to systemic flow ratio showed a median of 1.4 (range 0.6 to 1.9) (Table I).

Since 1982, 24 of the last 28 consecutive patients were diagnosed by cross-sectional echocardiography alone. There were 11 with supracardiac and 6 with infracardiac drainage. Pulmonary venous connection was directly to the coronary sinus in 9, whereas 2 patients had mixed anomalous drainage. Cardiac catheterization and angiography were undertaken in 4 patients because the attending physician lacked confidence in the echocardiographic diagnosis or the examamination was technically unsatisfactory.

Operative technique: Two methods of perfusion were employed for surgery. The first, used in 15 patients, was conventional cardiopulmonary bypass with moderate hypothermia and continuous perfusion. The second was surface cooling followed by limited perfusion, profound hypothermia and circulatory arrest. In all patients the heart was exposed through a conventional vertical median sternotomy.

Immediate postoperative management: An indwelling pulmonary arterial monitoring line was placed at surgery in all patients with suspected or proven high pulmonary arterial pressure and pulmonary vascular resistance. Pulmonary hypertensive crises were recognized and treated in 10 patients. Seven had supracardiac and 3 coronary sinus forms of TAPVC. These crises were manifest by a sudden major clinical deterioration associated with an increase in pulmonary artery pressure to systemic or suprasystemic levels with concomitant evidence of a decrease in cardiac output not precipitated by hypercapnia or hypoxia.[9] In 8 patients, an initial infusion of tolazoline hydrochloride as a bolus of 1 to 2 mg/kg followed by continuous intravenous infusion at 1 to 2 mg/kg resulted in a major improvement in the clinical status associated with a decrease in pulmonary pressure and a reduction in the ratio of pulmonary artery to systemic artery pressure. Three out of 10 patients treated for this complication eventually died.

Late reoperations: Reoperation was necessary in 7 patients. In group 1, 3 patients required the closure of a residual atrial septal defect and 1 underwent obliteration of a persistent left superior vena cava. Two patients in group 3 required reoperation, in 1 case for correction of a persistent atrial septal defect and in the other for redirection of the inferior vena caval inflow into the right atrium, after it had been inadvertently

TABLE II Age at Operation with Hospital Mortality

Age at Operation	All Pt (n = 83)	Group 1 Supracardiac (n = 32)	Group 2 Infracardiac (n = 16)	Group 3 Coronary Sinus (n = 27)	Group 4 Mixed (n = 8)
1–7 days	10 (1)	2 (0)	5 (1)	3 (0)

baffled into the left atrium at the original operation. One patient in group 4 required closure of an atrial septal defect. In 4 of the patients with a residual atrial septal defect a right/left transatrial approach was used together with enlargement of the atrial septum.

Statistical methods: Because the samples were independent, the median test, the Wilcoxon Rank Sum test, the Wald-Wolfowitz Runs test and the Komolgorov-Smirnov 2-sample test were used to consider differences. When the data was binary, the chi-square analysis or Fisher's exact tests were used. Results were appraised throughout on a 1-tailed basis. When the total of 83 patients is split into groups the numbers become rather small (e.g., for group 4, n = 8 only) and a statistical result which is not significant but which does show a trend might justify being regarded as not proven.

Results

Of the 83 patients, 12 (14%) died within 30 days of surgery. There were 2 deaths in group 1, 5 in group 2, 3 in group 3 and 2 in group 4 (Table II and III). Causes of death were refractory low cardiac output (4), recurrent pulmonary hypertensive crises (3), supraventricular arrhythmias (1), acute renal failure (1) and cardiac failure (1). Six patients died >30 days after surgery. In 2 of them there was pulmonary venous obstruction at the site of the anastomosis, between the pulmonary venous confluence and the morphological left atrium. Death occurred 2.5 months and 6.5 years after the operation. The cause of death in the remaining 4 was not known.

Actuarial analysis of long-term survival showed that the probability of survival, based on all 83 patients entering the study, was 75% at 84 months. Similar figures were obtained for groups 1, 3 and 4. However, the probability of survival of the 13 patients in group 2 was 60% at 72 months.

Analysis of risk factors: Statistical analysis in regard to survival within the 30-day hospital period was applied to a number of "supposed" risk factors. These were sex of patient, year of operation in the series, age at operation, height and weight (each expressed as percentiles), body surface area, number of days in the hospital prior to operation and systemic arterial pH on admission. Also included were the pulmonary artery systolic pressure and pulmonary vascular resistance in those patients who had undergone cardiac catheterization. We also took into account the method of diagnosis—cardiac catheterization, cross-sectional echocardiography alone and clinical evaluation. Finally, we analyzed the following variables: type of perfusion used, surgical approach, occurrence of pulmonary hypertensive crisis, anatomy of the defect, presence of cyanosis and heart failure, need for preoperative ventilation and presence of preoperative or postoperative renal failure.

The following factors showed a significant difference regarding survival within the 30-day hospital period for the whole group of patients. Risk of hospital death was greater in group 2 ($p < 0.009$). The presence of postoperative pulmonary hypertensive crises had significance ($p < 0.01$), the first 3 years of the study (1973–1975) having a higher risk than the remaining years and with the break at 1975/1976 ($p < 0.02$); it was also shown that females were more at risk than males ($p < 0.05$). Preoperative heart failure ($p < 0.01$) and preoperative renal failure ($p < 0.001$) were additional risk factors influencing survival. The only factor that improved the chance of survival was a diagnosis made on the basis of cross-sectional echocardiography without cardiac catheterization ($p < 0.05$).

Four of the last 28 patients have undergone cardiac catheterization. One of them died in the early postoperative period from obstructed pulmonary venous return.

Discussion

Retrospective statistical analysis of "risk factors" in the whole group of 83 patients shows 7 significant factors influencing successful surgical treatment. There was a higher incidence of death among female patients ($p < 0.05$). The year of operation was important in that there was a striking decrease in mortality from 1976 onwards ($p < 0.02$) reflecting chronological issues, in retrospective analysis of biomedical data.[10] The presence of pulmonary hypertensive crises in the postoperative period was another determinant of outcome because of the high probability of hospital death accompanying them ($p < 0.01$). Heart failure ($p < 0.01$) and preoperative renal failure ($p < 0.001$) similarly influenced survival by increasing the risk of hospital death. Only when the patients were diagnosed by cross-sectional echocardiography alone and were not submitted to conventional cardiac catheterization and angiography was there a significant improvement in survival ($p < 0.05$). Thus, of the 19 factors analyzed, 7 were significant.

Analyses of the 32 patients with supracardiac TAPVC showed that only postoperative pulmonary hypertensive crisis was a significant determinant of unsuccessful treatment ($p < 0.05$). Similarly, in those 27 patients with total anomalous pulmonary venous drainage to coronary sinus there was only 1 statistically significant factor influencing mortality: preoperative heart failure ($p < 0.05$), defined in this study as liver enlargement and a respiratory rate of >40 per minute. Analysis of risk factors in patients with the infracardiac type of anomaly showed a higher mortality in females ($p < 0.02$) and a greater risk of death before 1976 ($p < 0.02$). A raised pulmonary artery systolic pressure ($p < 0.1$) also increased the probability of death. That female patients were apparently disadvantaged may reflect their low weight and body surface area, although this could not be demonstrated statistically.

From 1973 to 1975, the treatment of 13 patients in our series resulted in a hospital mortality of 46%. Since that time, 70 patients have been treated with a mortality of 8.5%, giving a current overall mortality of 14% over a 13-year period. This in part may reflect the "era effect" on the unit and its personnel.[10]

The risk of surgical death is greatly increased in patients with infracardiac anomalous connection. This largely reflects the aforementioned risk factors because the surgical technique to repair the defect is not dissimilar to that for other forms of TAPVC. The recognition of postoperative pulmonary hypertensive crises in 1978 established that these patients are at risk from them and that they can be effectively treated by specific pharmacological agents.[9] The work of Haworth and Newfeld showed that structural changes in pulmonary arterial and venous channels reflecting pulmonary vascular disease may be present in neonates and infants, including TAPVC.[11,12] Newfeld's observation that the degree of pulmonary vascular disease found at autopsy did not correlate well with the pulmonary to systemic systolic blood pressure ratio at cardiac catheterization lends credence to our own observations that patients with preoperative pulmonary artery pressure and pulmonary vascular resistance within normal limits may experience postoperative pulmonary hypertensive crises. The physiological implication of these pulmonary vascular changes is a highly reactive pulmonary vascular bed. We consider it important, therefore, to monitor the pulmonary artery pressure during the early postoperative period.

In the last 28 consecutive patients treated in this series, only 4 were investigated by conventional cardiac catheterization and angiography for the reasons already outlined. The remainder underwent surgery when the diagnosis was established by cross-sectional echocardiography alone. There was 1 mistake in the type of anatomy suggested by this technique but no patient died. In our analysis of risk factors, investigation by cross-sectional echocardiography alone was the only significant factor in improving the chance of survival. Although the surgical treatment of TAPVC solely on the basis of cross-sectional echocardiography has been reported,[13] it was not considered at that time to be significant in improving survival. Our study has shown that by avoiding cardiac catheterization surgical mortality is significantly reduced. It is our current practice, therefore, always to use cross-sectional echocardiography as the final arbiter in the diagnosis of TAPVC.

Acknowledgment: We wish to thank Margaret Rehahn, RIS, for performing the statistical analysis. We also wish to thank our many colleagues in medicine, nursing and paramedical specialities who have helped us in the treatment of these patients.

Accuracy of Electrical Impedance Cardiography for Measuring Cardiac Output in Children with Congenital Heart Defects

DANIEL S. MILES, PhD, ROBERT W. GOTSHALL, PhD, JANE C. GOLDEN, MS, DWIGHT T. TUURI, MD, ROBERT H. BEEKMAN III, MD, and TERRENCE DILLON, MD

This study determined whether noninvasive electrical impedance cardiography accurately measures systemic blood flow (cardiac output) in children with congenital heart defects. A total of 37 patients ranging in age from 2 to 171 months underwent complete right- and left-sided heart catheterizations that included simultaneous Fick and impedance measurement of cardiac output. Based on the diagnosis, 4 groups were formed consisting of a control group (n = 11) with no shunts, a group with intracardiac left-to-right shunting and an atrial septal defect (n = 7), another with a ventricular septal defect (n = 12) and an extracardiac left-to-right shunting with patent ductus arteriosus group (n = 7). Impedance values for systemic blood flow were compared with systemic and pulmonary blood flow obtained by the direct Fick method with measured oxygen consumption. The difference between impedance and Fick systemic blood flow was ≤5% in each of the 4 groups. The highest correlation between impedance and Fick systemic blood flow was with the atrial septal defect group (r = 0.89) and lowest with the ventricular septal defect and control (r = 0.69) groups. Fick pulmonary blood flow was significantly greater than impedance or Fick systemic flow in all 3 shunt groups. Impedance cardiography accurately measured systemic blood flow in children without shunts or valvular insufficiency. Likewise, systemic blood flow was accurately measured by impedance in the presence of intracardiac left-to-right shunts (atrial and ventricular septal defects) and extracardiac left-to-right shunts (patent ductus arteriosus). Although such results are promising, further studies are needed to evaluate the role of impedance cardiography in pediatric medicine.

(Am J Cardiol 1988;61:612–616)

Impedance cardiography is a noninvasive technique used to measure stroke volume on a beat-by-beat basis.[1-4] Most validation studies[1,5,6,7] and clinical trials[8,9] have used adults or animal models almost exclusively. The application of this technique in a neonatal or pediatric population has received very little attention.[10-15] Due to its ease of application, cost effectiveness and atraumatic nature, impedance cardiography may provide an effective adjunct for assessing a child's cardiovascular status or response to medical or surgical therapy.

Our preliminary work with canine pups[6] and neonates[16] suggested that the impedance technique may prove useful in measuring cardiac output in premature newborns, neonates and children. We were particularly interested in evaluating whether the impedance technique could measure cardiac output in children with a congenital heart defect. The only previous study to evaluate children with congenital heart defects reported that the impedance technique overestimated systemic flow but correlated well with pulmonary flow.[14] Unfortunately, because oxygen consumption was estimated in that study,[14] the Fick blood flow measurements may have been questionable. The present study determines whether impedance cardiography accurately measures cardiac output in the presence of

either intracardiac or extracardiac shunting in children with congenital heart defects.

Methods

Patients: All participants underwent complete right- and left-sided heart catheterizations to confirm the diagnosis, evaluate the extent of a congenital defect or determine the success of corrective surgery. All catheterizations were completed at The Children's Medical Center. Approval for this study was obtained from the Wright State University's Human Subjects Institutional Review Board and the hospital's review board. A total of 37 participants were divided into 4 groups based on the diagnosis. No shunts were present in a control group of patients (n = 11) presenting with a variety of disorders, such as aortic or pulmonary stenosis or aortic coarctation, as well as successfully repaired shunts. Intracardiac shunts were present in the secundum atrial septal defect (ASD) group (n = 7) and in the ventricular septal defect (VSD) group (n = 12). Extracardiac shunts occurred with patent ductus arteriosus (PDA) patients (n = 7). Descriptive characteristics are listed in Table I.

Catheterization: The patients were sedated preoperatively with a variety of medications such as morphine, vistaril, chlorohydrate or ketamine. The right femoral vein was used for right-heart catheterization. The inguinal region was infiltrated with 1 to 2% xylocaine or lidocaine before percutaneous insertion of a Berman or Edwards angiographic catheter (4 to 8Fr) and passed with the aid of fluoroscopy. Left-heart catheterization was performed by inserting a regular Cook pigtail catheter (3 to 6 Fr) into the femoral artery. Pressures were measured with a fluid-filled transducer and recorded on a 4-channel oscillographic recorder (Electronics for Medicine).

Cardiac output: Systemic and pulmonary blood flows were measured by the direct Fick procedure. The direction and magnitude of shunting were also calculated using this procedure, with the superior vena cava providing the mixed venous sample. Oxygen saturation was measured (American Optical Unistat Oximeter) using 0.25 ml aliquots of blood. Blood oxygen carrying capacity was calculated as hemoglobin (g/dl) × 1.36. Oxygen consumption was measured with a Waters instruments continuous flow-through head-box system (MRM2 - O_2 Consumption Monitor). An average of three 1-minute samples was used in the calculations.

TABLE I Descriptive Characteristics (Mean ± Standard Error and Range) of the Patients

Pt	Control (n = 11)	ASD (n = 7)	VSD (n = 12)	PDA (n = 7)
Age (mo)	58 ± 12 (6–130)	72 ± 22 (6–171)	32 ± 9 (2–90)	39 ± 12 (9–88)
Height (cm)	100 ± 7 (63–140)	109 ± 14 (57–164)	86 ± 6 (56–120)	89 ± 7 (68–107)
Weight (kg)	16.7 ± 3 (5–35)	25.7 ± 7 (8–60)	11.8 ± 2 (4–20)	12.7 ± 1.8 (6–20)

ASD = atrial septal defect; control = no shunts; PDA = patent ductus arteriosus; VSD = ventricular septal defect.

Cardiac output was measured by impedance at the time of the oxygen consumption measurements.[17] Mylar tape electrode strips were positioned on the forehead, circumferentially around the neck and on a midaxillary to midaxillary line at the level of the xiphisternal notch and lower abdomen (Figure 1). The Minnesota Impedance Cardiograph Model 304B was used to introduce a constant sinusoidal alternating current of 4 mA at 100 kHz between the outer 2 electrodes (the inner electrodes are sensing electrodes and detect changes in voltage). Knowing the current applied and voltage produced, the cardiograph calculates the impedance based on Ohm's law. Heart sounds were measured at the lower sternal border using a Hewlett Packard microphone (21050 A) and the electrocardiogram was obtained from an Electronics for Medicine ECG amplifier.

The electrical impedance technique provides real-time values of stroke volume which are used with the heart rate to determine cardiac output.[2,4] The stroke volume is derived from analysis of the change in impedance with respect to time (dZ/dt) during the cardiac cycle. The electrocardiogram, phonocardiogram and dZ/dt were recorded at a paper speed of 100 mm/s with a Gould 4-channel strip-chart recorder (Figure 1). The equation used to calculate stroke volume was $SV = p \cdot (L/Z_0)^2 \cdot dZ/dt \cdot T$ and expressed as follows: $SV = (\Omega \cdot cm)(cm^2/\Omega^2)(\Omega/s)(s) = cm^3$ (ml), where SV = stroke

TABLE II Summary (Mean ± Standard Error and Range) of the Catheterization Procedure

	HR	$\dot{V}O_2$	$\dot{Q}PI/\dot{Q}SI$	LRS	RLS	RP/RS

HR = heart rate (beats/min); LRS = left-to-right shunt (liters/min/m^2); $\dot{Q}PI/\dot{Q}SI$ = ratio of pulmonary to systemic cardiac index; RLS = right-to-left shunt (liters/min/m^2); RP/RS = ratio of pulmonary to systemic resistance; $\dot{V}O_2$ = oxygen consumption (cc/min/m^2). Other abbreviations as in Table I.

TABLE III Summary (Mean ± Standard Error and Range) of Direct Fick and Impedance Blood Flow

	$\dot{Q}S$	$\dot{Q}Z$	$\dot{Q}P$
Control	3.09 ± 0.45 (0.96–5.17)	3.22 ± 0.59 (0.41–6.31)	3.09 ± 0.45 (0.96–5.17)
ASD	2.72 ± 0.49 (0.36–4.10)	2.86 ± 0.71 (0.41–5.62)	6.56* ± 1.30 (1.63–10.96)
VSD	2.59 ± 0.36 (0.87–4.51)	2.52 ± 0.48 (0.26–5.95)	5.02* ± 0.47 (1.97–7.33)
PDA	2.48 ± 0.35 (1.34–3.75)	2.49 ± 0.44 (0.90–3.76)	4.51* ± 0.62 (2.46–6.51)

* $p < 0.05$, $\dot{Q}P > \dot{Q}S$ or $\dot{Q}Z$.

$\dot{Q}P$ = Fick pulmonary blood flow (liters/min); $\dot{Q}S$ = Fick systemic blood flow (liters/min); $\dot{Q}Z$ = impedance systemic blood flow (liters/min). Other abbreviations as in Table I.

volume (ml); p = resistivity (Ω · cm) of blood and assumed to be a constant[18] of 135; L = anterior midline distance between the inner electrodes (cm); Z_0 = total thoracic impedance (Ω) between the sensing electrodes (2 and 3); dZ/dt = the maximum rate of change of the thoracic impedance (Ω/s) during each heart beat measured from the beginning of the rapid upstroke independent of the calibration baseline as previously described in our laboratory[19]; T = left ventricular ejection time (s).

Heart rate was determined on a beat-by-beat basis from the Q-Q interval of the electrocardiogram and multiplied by stroke volume to obtain impedance systemic blood flow. The mean impedance blood flow was obtained by averaging 10 heartbeats. Impedance data were hand-digitized on a Houston Instruments True Grid 1017 digitizing pad interfaced with an IBM-PC XT computer.

Statistical analyses: Means, standard errors, regression analysis, correlations and Student-dependent *t* test were run using the Crunch Interactive Statistical Package (CRISP). All null hypotheses were rejected at the 5% level.

Results

Heart rates for the 4 groups were similar during catheterization (Table II). The greater Fick pulmonary blood flow in the ASD, VSD and PDA groups (compared with Fick systemic blood flow) could be attributed to the left-to-right shunting. The ratio of pulmonary resistance to systemic resistance was similar in all groups.

The systemic blood flow measured by impedance was similar ($r = 0.84$, $p < 0.05$) to Fick measurements (Table III, Figure 2). The difference between the blood flow values for the 2 techniques was ≤5% in each of the 4 groups (Figure 3). Blood flow correlations between the 2 techniques ranged from 0.69 to 0.89, with the highest in the ASD group and lowest in the VSD

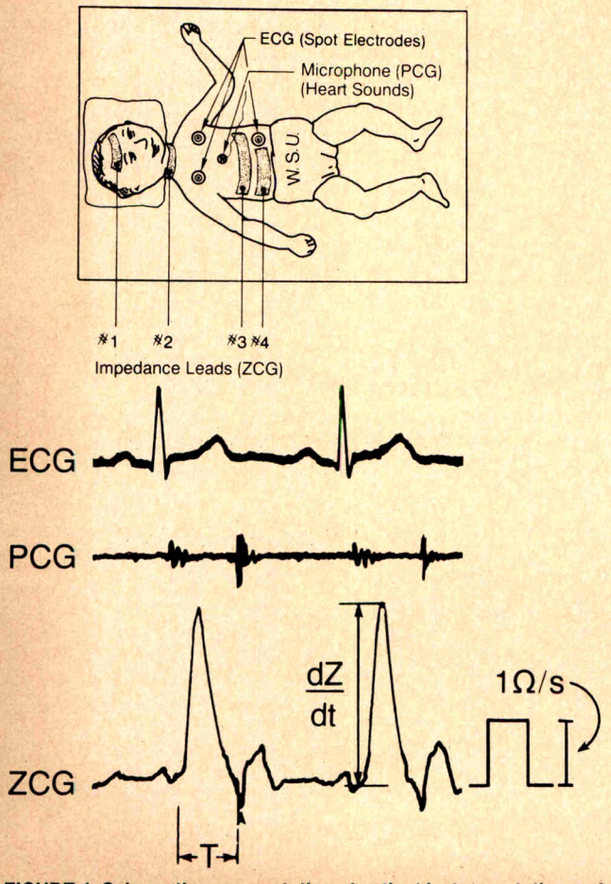

FIGURE 1. Schematic representation of patient instrumentation and records of the electrocardiogram (ECG), phonocardiogram (PCG) and impedance cardiogram (ZCG).

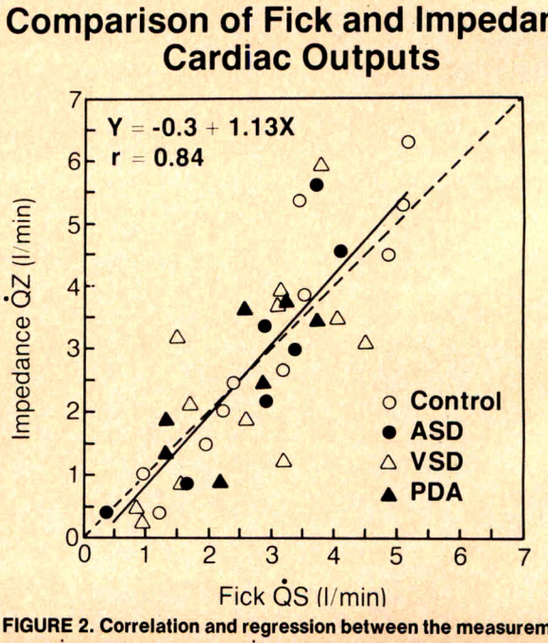

FIGURE 2. Correlation and regression between the measurement of Fick ($\dot{Q}S$) and impedance ($\dot{Q}Z$) systemic blood flow for all subjects including atrial septal defects (ASD), ventricular septal defects (VSD), patent ductus arteriosus (PDA) and no shunts (control).

and control groups. Fick pulmonary blood flow was significantly greater than systemic flow as determined by either Fick or impedance in the ASD, VSD and PDA groups (Table III, Figure 3).

Discussion

Repeated tests can be easily administered using the impedance technique for assessment of cardiac output without any known risk or discomfort to the patient. It may prove to be particularly useful in providing a means to serially evaluate patients after surgery or over the course of medical or surgical management. It must be convincingly demonstrated, however, that an accurate estimate of cardiac output is being measured. The present patient population offered an opportunity to evaluate the impedance technique using the established direct Fick procedure as the standard. Nevertheless, it should be noted that even blood flow measured by the direct Fick procedure is not without inherent errors.

Very few studies evaluating neonates or children with impedance cardiography have been published. We have previously reported that healthy premature infants weighing 0.8 to 3.8 kg could be evaluated accurately.[16] Premature infants with patent ductus arteriosus,[20,21] healthy newborn infants[11,12,22] and children[23] also have been studied. In general, these studies have reported cardiac output values consistent with the population under consideration but lacked a comparison with an invasive technique. The work of Lababidi et al[14] is the only other study published where a comparison between direct Fick values of cardiac output and impedance has been evaluated in children with and without cardiac shunts.

Our results were similar to Lababidi et al in demonstrating that cardiac outputs measured by either the Fick or impedance techniques were similar (r = 0.69) in children without shunts or valvular insufficiency. Our results were at variance, however, with their values reported for children with intracardiac left-to-right shunting. When they evaluated 21 patients with left-to-right shunts, the impedance cardiac output overestimated systemic flow and correlated well with pulmonary blood flow (r = 0.92) rather than systemic flow (r = 0.21). In sharp contrast, our findings suggested close agreement between the Fick and impedance systemic blood flow measurements in either the ASD (r = 0.89) or VSD (r = 0.69) groups.

The reason for the discrepancy between the 2 studies of patients with intracardiac shunts is not readily apparent. Oxygen consumption was directly measured in the present study whereas in the Labibidi et al study it was estimated. It has been demonstrated that oxygen consumption in sedated children varies during catherization procedures[24] and that oxygen consumption is higher in children with cardiovascular disease.[25] If oxygen consumption was underestimated by Lababidi et al, Fick estimates of pulmonary and systemic flow would also be underestimated. Perhaps this may explain some of the observed differences. Furthermore, we used a constant of 135 Ω · cm for the blood resistivity factor in our calculation of stroke volume,[18] whereas Lababidi et al based blood resistivity calculations on the hematocrit. The total number of patients evaluated with intracardiac shunts was only 19 in the present study and 21 in Lababidi's. Clearly, further data are needed before a definitive conclusion can be drawn.

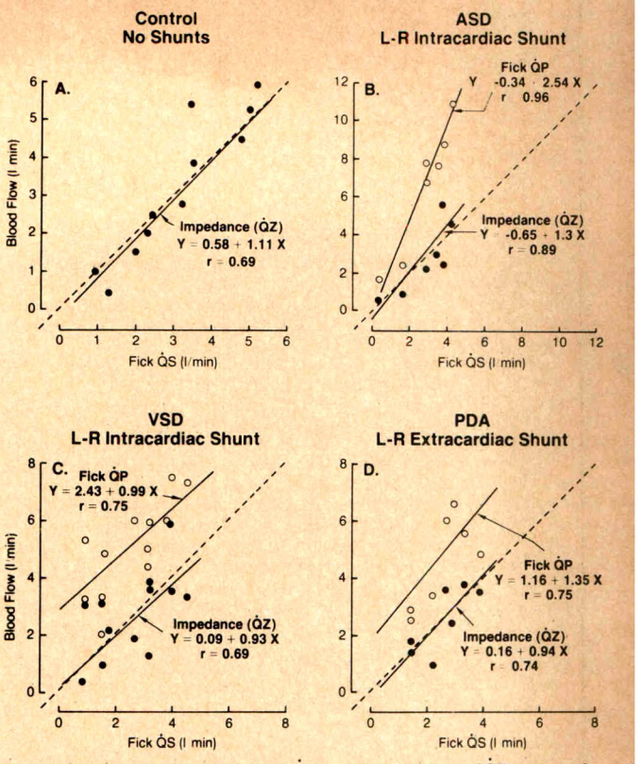

FIGURE 3. Individual systemic (Q̇S) and pulmonary (Q̇P, open circles) blood flow determined by the Fick procedure, and systemic blood flow determined by impedance (Q̇Z) for (*A*) control, (*B*) atrial septal defect (ASD), (*C*) ventricular septal defect (VSD) and (*D*) patent ductus arteriosus (PDA) groups.

In the patients with PDA (extracardiac left-to-right shunts), impedance measurements reflected systemic blood flow (r = 0.74). Pulmonary blood flow measured by the Fick technique was consistently higher than either Fick or impedance systemic flow in all patients. These results were again at variance with the only 2 previously published studies of patent ductus arteriosus patients.[20,21] Cotton et al[20] reported that the magnitude of the ΔZ signal using a tetrapolar electrode configuration was indicative of pulmonary blood flow in infants with symptomatic PDA. Spontaneous or pharmacologic closure of the ductus was coincident with an amplitude decrease in the ΔZ signal. Cardiac output, however, was not measured. Sexson et al[21] demonstrated in a preliminary report that indomethacin significantly reduced cardiac output within 24 hours of therapy for treatment of PDA. Neither the study by Cotton et al[20] nor Sexson et al[21] used an alternative technique for corroboration of the impedance values.

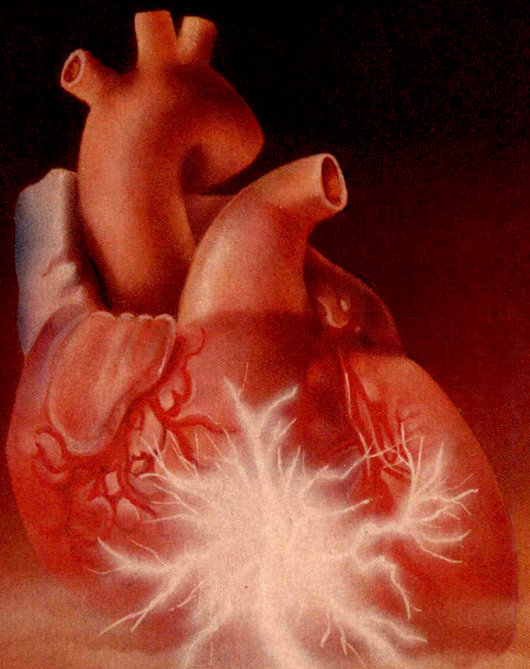
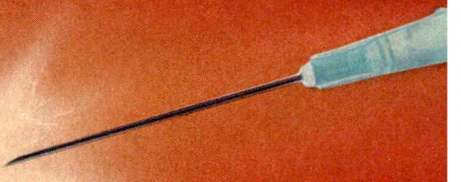
Help while it's happening...





436-8066-A

in Acute MI

Geigy

Lifesaving

- 36% reduction in 3-month mortality[1]
- Reduced incidence of arrhythmias and ischemic pain[1]

Safe

- >93% tolerated the full intravenous dose[2]
- <1% withdrawn for congestive heart failure[3]

Intravenous followed by long-term oral therapy

Alternatively, oral treatment can begin within 3 to 10 days of the acute event

Lopressor is contraindicated in patients with heart rate <45 beats/min; second- and third-degree heart block; significant first-degree heart block (P-R interval ≥0.24 sec); systolic blood pressure <100 mmHg; or moderate-to-severe cardiac failure.

Please see last page for Brief Summary of Prescribing Information.

The *only* beta blocker indicated in definite or suspected acute myocardial infarction...

Lopressor® in MI

metoprolol tartrate

Prefilled Syringes: 5 mg/5 ml
Ampuls: 5 mg/5 ml
Tablets: 100 mg 50 mg

Changing the Course of Cardiovascular Care

Lopressor®

metoprolol tartrate USP

Tablets
Ampuls
Prefilled Syringes

BRIEF SUMMARY
(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

INDICATIONS AND USAGE

Hypertension
Lopressor tablets are indicated for the treatment of hypertension. They may be used alone or in combination with other antihypertensive agents.

Angina Pectoris
Lopressor is indicated in the long-term treatment of angina pectoris.

Myocardial Infarction
Lopressor ampuls, prefilled syringes, and tablets are indicated in the treatment of hemodynamically stable patients with definite or suspected acute myocardial infarction to reduce cardiovascular mortality. Treatment with intravenous Lopressor can be initiated as soon as the patient's clinical condition allows (see **DOSAGE AND ADMINISTRATION, CONTRAINDICATIONS,** and **WARNINGS**). Alternatively, treatment can begin within 3 to 10 days of the acute event (see **DOSAGE AND ADMINISTRATION**).

CONTRAINDICATIONS

Hypertension and Angina
Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **WARNINGS**).

Myocardial Infarction
Lopressor is contraindicated in patients with a heart rate < 45 beats/min; second- and third-degree heart block; significant first-degree heart block (P-R interval ≥ 0.24 sec); systolic blood pressure < 100 mmHg; or moderate-to-severe cardiac failure (see **WARNINGS**).

WARNINGS

Hypertension and Angina
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive and angina patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and Lopressor slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic. The response should be observed closely. If cardiac failure continues, despite adequate digitalization and diuretic therapy, Lopressor should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have occurred. When discontinuing chronically administered Lopressor, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of 1-2 weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Lopressor administration should be reinstated promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Lopressor therapy abruptly even in patients treated only for hypertension.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly, and the lowest possible dose of Lopressor should be used. In these circumstances it would be prudent initially to administer Lopressor in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See DOSAGE AND ADMINISTRATION.)**

Major Surgery: The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial; the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Lopressor, like other beta blockers, is a competitive inhibitor of beta-receptor agonists, and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes and Hypoglycemia: Lopressor should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade, which might precipitate a thyroid storm.

Myocardial Infarction
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function, and beta blockade carries the potential hazard of depressing myocardial contractility and precipitating or exacerbating minimal cardiac failure.

During treatment with Lopressor, the hemodynamic status of the patient should be carefully monitored. If heart failure occurs or persists despite appropriate treatment, Lopressor should be discontinued.

Bradycardia: Lopressor produces a decrease in sinus heart rate in most patients; this decrease is greatest among patients with high initial heart rates and least among patients with low initial heart rates. Acute myocardial infarction (particularly inferior infarction) may in itself produce significant lowering of the sinus rate. If the sinus rate decreases to < 40 beats/min, particularly if associated with evidence of lowered cardiac output, atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, Lopressor should be discontinued, and cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

AV Block: Lopressor slows AV conduction and may produce significant first- (P-R interval ≥0.26 sec), second-, or third-degree heart block. Acute myocardial infarction also produces heart block.

If heart block occurs, Lopressor should be discontinued and atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

Hypotension: If hypotension (systolic blood pressure ≤ 90 mmHg) occurs, Lopressor should be discontinued, and the hemodynamic status of the patient and the extent of myocardial damage carefully assessed. Invasive monitoring of central venous, pulmonary capillary wedge, and arterial pressures may be required. Appropriate therapy with fluids, positive inotropic agents, balloon counterpulsation, or other treatment modalities should be instituted. If hypotension is associated with sinus bradycardia or AV block, treatment should be directed at reversing these (see above).

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, Lopressor may be used with extreme caution in patients with bronchospastic disease. Because it is unknown to what extent beta$_2$-stimulating agents may exacerbate myocardial ischemia and the extent of infarction, these agents should *not* be used prophylactically. If bronchospasm not related to congestive heart failure occurs, Lopressor should be discontinued. A theophylline derivative or a beta$_2$ agonist may be administered cautiously, depending on the clinical condition of the patient. Both theophylline derivatives and beta$_2$ agonists may produce serious cardiac arrhythmias.**

PRECAUTIONS

General
Lopressor should be used with caution in patients with impaired hepatic function.

Information for Patients
Patients should be advised to take Lopressor regularly and continuously, as directed, with or immediately following meals. If a dose should be missed, the patient should take only the next scheduled dose (without doubling it). Patients should not discontinue Lopressor without consulting the physician.

Patients should be advised (1) to avoid operating automobiles and machinery or engaging in other tasks requiring alertness until the patient's response to therapy with Lopressor has been determined; (2) to contact the physician if any difficulty in breathing occurs; (3) to inform the physician or dentist before any type of surgery that he or she is taking Lopressor.

Laboratory Tests
Clinical laboratory findings may include elevated levels of serum transaminase, alkaline phosphatase, and lactate dehydrogenase.

Drug Interactions
Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension or marked bradycardia, which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility
Long-term studies in animals have been conducted to evaluate carcinogenic potential. In 2-year studies in rats at three oral dosage levels of up to 800 mg/kg per day, there was no increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes that appeared to be drug related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in Swiss albino mice at three oral dosage levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant or total (benign plus malignant) lung tumors, nor in the overall incidence of tumors or malignant tumors. This 21-month study was repeated in CD-1 mice, and no statistically or biologically significant differences were observed between treated and control mice of either sex for any type of tumor.

All mutagenicity tests performed (a dominant lethal study in mice, chromosome studies in somatic cells, a Salmonella/mammalian-microsome mutagenicity test, and a nucleus anomaly test in somatic interphase nuclei) were negative.

No evidence of impaired fertility due to Lopressor was observed in a study performed in rats at doses up to 55.5 times the maximum daily human dose of 450 mg.

Pregnancy Category C
Lopressor has been shown to increase postimplantation loss and decrease neonatal survival in rats at doses up to 55.5 times the maximum daily human dose of 450 mg. Distribution studies in mice confirm exposure of the fetus when Lopressor is administered to the pregnant animal. These studies have revealed no evidence of impaired fertility or teratogenicity. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers
Lopressor is excreted in breast milk in very small quantity. An infant consuming 1 liter of breast milk daily would receive a dose of less than 1 mg of the drug. Caution should be exercised when Lopressor is administered to a nursing woman.

Pediatric Use
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Hypertension and Angina
Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression has been reported in about 5 of 100 patients. Mental confusion and short-term memory loss have been reported. Headache, nightmares, and insomnia have also been reported.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations; congestive heart failure; peripheral edema; and hypotension have been reported in about 1 of 100 patients. (See **CONTRAINDICATIONS, WARNINGS,** and **PRECAUTIONS**.)

Respiratory: Wheezing (bronchospasm) and dyspnea have been reported in about 1 of 100 patients (see **WARNINGS**).

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, dry mouth, gastric pain, constipation, flatulence, and heartburn have been reported in about 1 of 100 patients.

Hypersensitive Reactions: Pruritus or rash have occurred in about 5 of 100 patients. Worsening of psoriasis has also been reported.

Miscellaneous: Peyronie's disease has been reported in fewer than 1 of 100,000 patients. Musculoskeletal pain, blurred vision, and tinnitus have also been reported.

There have been rare reports of reversible alopecia, agranulocytosis, and dry eyes. Discontinuation of the drug should be considered if any such reaction is not otherwise explicable.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor.

Myocardial Infarction
Central Nervous System: Tiredness has been reported in about 1 of 100 patients. Vertigo, sleep disturbances, hallucinations, headache, dizziness, visual disturbances, confusion, and reduced libido have also been reported, but a drug relationship is not clear.

Cardiovascular: In the randomized comparison of Lopressor and placebo described in the **CLINICAL PHARMACOLOGY** section, the following adverse reactions were reported:

	Lopressor	*Placebo*
Hypotension (systolic BP < 90 mmHg)	27.4%	23.2%
Bradycardia (heart rate < 40 beats/min)	15.9%	6.7%
Second- or third-degree heart block	4.7%	4.7%
First-degree heart block (P-R ≥ 0.26 sec)	5.3%	1.9%
Heart failure	27.5%	29.6%

Respiratory: Dyspnea of pulmonary origin has been reported in fewer than 1 of 100 patients.

Gastrointestinal: Nausea and abdominal pain have been reported in fewer than 1 of 100 patients.

Dermatologic: Rash and worsened psoriasis have been reported, but a drug relationship is not clear.

Miscellaneous: Unstable diabetes and claudication have been reported, but a drug relationship is not clear.

Potential Adverse Reactions
A variety of adverse reactions not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse reactions to Lopressor.

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **CONTRAINDICATIONS**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Hypersensitive Reactions: Fever combined with aching and sore throat, laryngospasm, and respiratory distress.

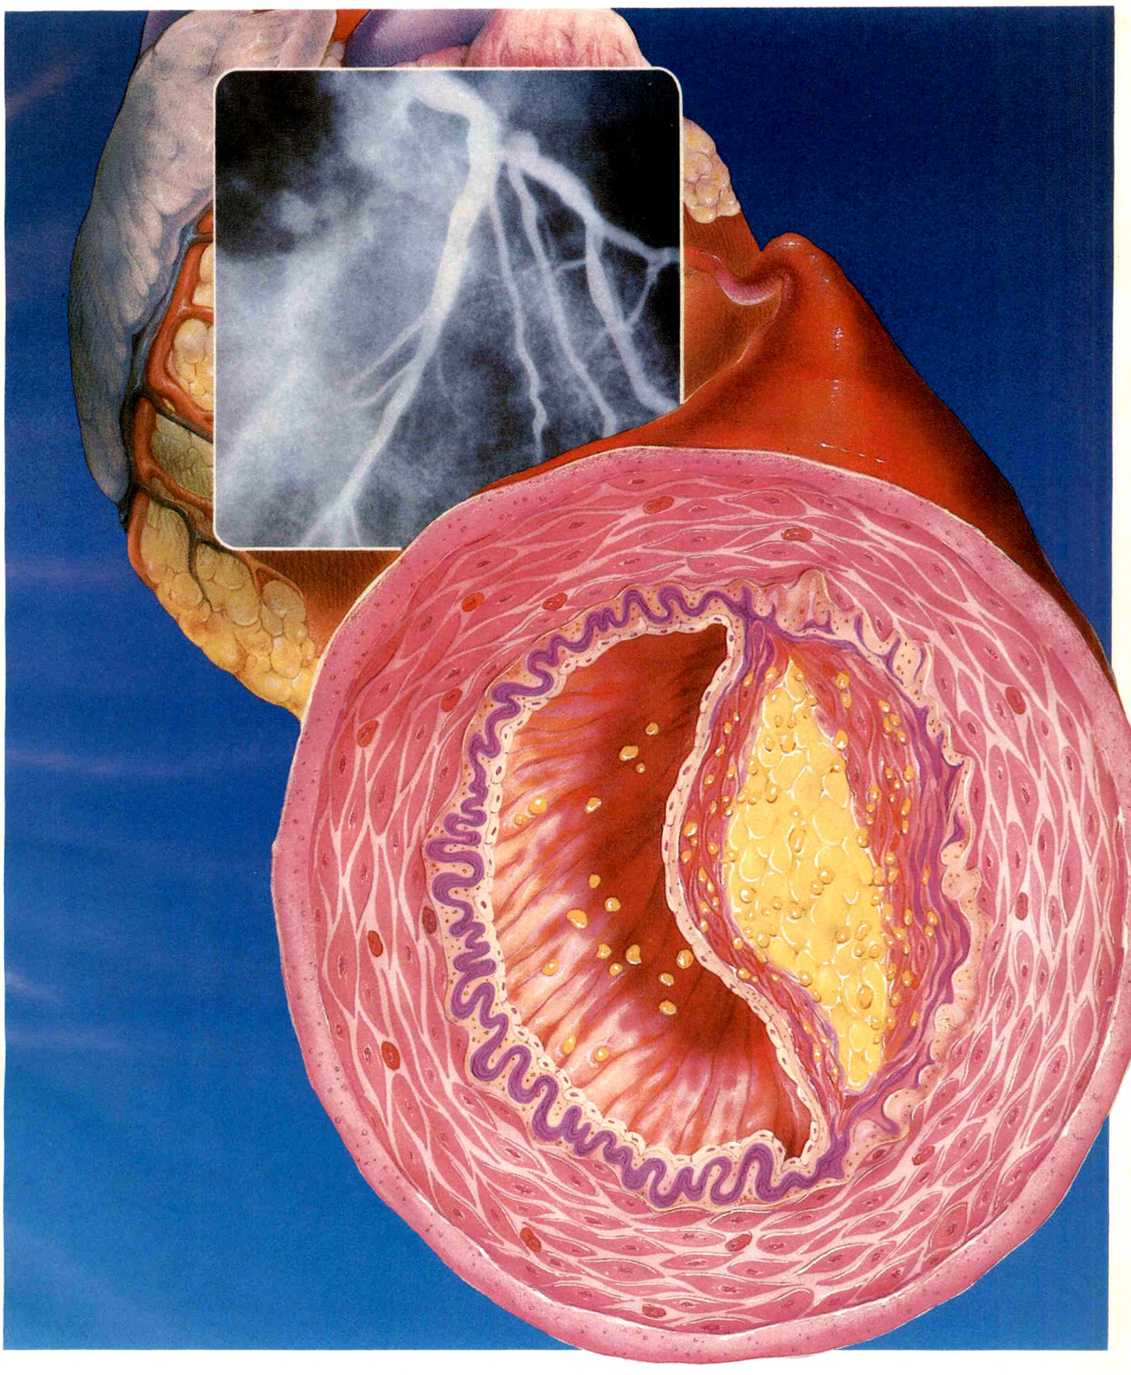
When the Goal Is to Reduce Elevated Blood Cholesterol...



LORELCO®
PROBUCOL 250 mg tablets

Prescribing Information appears on the last page.

Choose

LORELCO® PROBUCOL

250 mg tablets

as an adjunct to diet

Effectively Lowers Serum Cholesterol with a Unique Combination of Benefits

1 Efficacy

Lorelco works! You can prescribe it with confidence. Lorelco can virtually double the cholesterol-lowering efficacy of diet alone.[1] Total cholesterol-lowering efficacy *beyond diet* ranges from 10.7% to 27% in reported studies.[1-4]

2 Indications

Lorelco is specifically indicated for the reduction of elevated serum cholesterol in patients with primary hypercholesterolemia who have not responded adequately to diet.

Consider the Whole Picture.

Merrell Dow

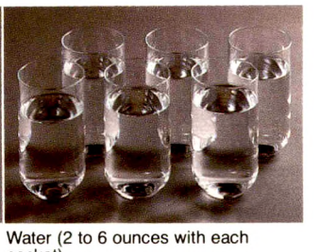
#1 selling lipid-lowering agent in the world

3 Compliance

The reasons for excellent compliance with Lorelco become clear with the taste and texture test.

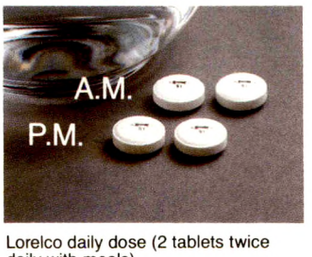
This

Questran daily dose (one 9-gram packet one to six times daily)



Water (2 to 6 ounces with each packet)

or This



Lorelco daily dose (2 tablets twice daily with meals)

Tablet counts in a 7 year study of Lorelco indicated that patients took over 90% of their scheduled dosage.[5]

4 Side Effects

Lorelco side effects are generally tolerable and of short duration.

Most frequent patient complaint is loose stools, which occur in about one in 10 patients and generally subside during therapy (see Prescribing Information for full discussion of side effects).

Lorelco is not an innocuous drug and strict attention should be paid to the Indications, Warnings, and Precautions.

5 Cost

The cost of Lorelco is significantly lower than that of the resins, lovastatin, and niacin tablets USV.

Cost can be a significant factor when therapy may have to be continued long-term, perhaps for years.

10 years of outstanding Lorelco performance[6]

Now prescribed in 27 countries

The effect of probucol-induced reduction of serum cholesterol or triglyceride levels or alteration of HDL-cholesterol levels on morbidity or mortality has not yet been established. Several years may be required before ongoing long-term investigations will resolve this question.

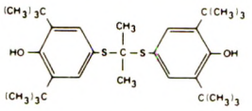
Lorelco® Tablets
(probucol tablets)

CAUTION: Federal law prohibits dispensing without prescription.

DESCRIPTION: Lorelco (probucol) film-coated tablets for oral administration contain 250 mg of probucol per tablet. Each tablet also contains as inactive ingredients: corn starch, ethylcellulose, glycerin, hydroxypropyl cellulose, hydroxypropyl methylcellulose 2910, iron oxide, lactose, magnesium stearate, microcrystalline cellulose, polysorbate 80, talc, and titanium dioxide. Lorelco is an agent for the reduction of elevated serum cholesterol. The chemical name is 4,4'-(isopropylidenedithio) bis (2,6-di-t-butylphenol). Its chemical structure does not resemble that of any other available cholesterol-lowering agent. It is lipophilic.



CLINICAL PHARMACOLOGY: Lorelco (probucol) lowers serum cholesterol and has relatively little effect on serum triglycerides. Patients responding to probucol exhibit a decrease in low density lipoprotein cholesterol. Cholesterol is reduced not only in the low density lipoprotein fraction, but also in some high density lipoprotein fractions with proportionately greater effect on the high density portion in some patients. Epidemiological studies have shown that both low HDL-cholesterol and high LDL-cholesterol are independent risk factors for coronary heart disease. The risk of lowering HDL-cholesterol while lowering LDL-cholesterol remains unknown. There is little or no effect reported on very low density lipoprotein.

Studies on the mode of action of Lorelco indicate that it increases the fractional rate of catabolism of low density lipoproteins. This effect may be linked to the observed increased excretion of fecal bile acids, a final metabolic pathway for the elimination of cholesterol from the body. Lorelco also exhibits inhibition of early stages of cholesterol synthesis and slight inhibition of absorption of dietary cholesterol. There is no increase in the cyclic precursors of cholesterol, namely desmosterol and 7-dehydrocholesterol. On this basis, it is concluded that Lorelco does not affect the later stages of cholesterol biosynthesis.

Absorption of Lorelco from the gastrointestinal tract is limited and variable. When it is administered with food, peak blood levels are higher and less variable. With continuous administration in a dosage of 500 mg b.i.d., the blood levels of an individual gradually increase over the first three to four months and thereafter remain fairly constant. In 116 patients treated with Lorelco for periods of three months to one year, the mean blood level was 23.6 ± 17.2 mcg/ml (± S.D.) ranging to 78.3 mcg/ml. Levels observed after seven years of treatment in 40 patients yielded an average value of 21.5 ± 16.5 mcg/ml (± S.D.) ranging to 62.0 mcg/ml.

At the end of 12 months of treatment in eight patients, blood levels averaged 19.0 mcg/ml. Six weeks after cessation of therapy, the average had fallen by 60 percent. After six months the average had fallen by 80 percent.

In December 1984 a National Institutes of Health Consensus Development Conference Panel† concluded that lowering definitely elevated blood cholesterol levels (specifically blood levels of low-density lipoprotein cholesterol) will reduce the risk of heart attacks due to coronary heart disease. The effect of probucol-induced reduction of serum cholesterol or triglyceride levels or alteration of HDL-cholesterol levels on morbidity or mortality due to coronary heart disease has not yet been established. Several years may be required before ongoing long-term investigations will resolve this question.

INDICATIONS AND USAGE: Serious animal toxicity has been encountered with probucol. See WARNINGS and ANIMAL PHARMACOLOGY AND TOXICOLOGY sections. Probucol is not an innocuous drug and strict attention should be paid to the INDICATIONS and WARNINGS.

Drug therapy should not be used for the routine treatment of elevated blood lipids for the prevention of coronary heart disease. Dietary therapy specific for the type of hyperlipidemia is the initial treatment of choice. Excess body weight may be an important factor and should be addressed prior to any drug therapy. Physical exercise can be an important ancillary measure. Contributory disease such as hypothyroidism or diabetes mellitus should be looked for and adequately treated. The use of drugs should be considered only when reasonable attempts have been made to obtain satisfactory results with non-drug methods. If the decision ultimately is to use drugs, the patient should be instructed that this does not reduce the importance of adhering to diet.

The selection of patients for cholesterol-lowering drug therapy should take into account other important coronary risk factors such as smoking, hypertension and diabetes mellitus. Consideration should be given to the efficacy, safety and compliance factors for each of the cholesterol-lowering drugs prior to selecting the one most appropriate for an individual patient.

Lorelco may be indicated for the reduction of elevated serum cholesterol in patients with primary hypercholesterolemia (elevated low density lipoproteins) who have not responded adequately to diet, weight reduction and control of diabetes mellitus. Lorelco may be useful to lower elevated cholesterol that occurs in patients with combined hypercholesterolemia and hypertriglyceridemia, but it is not indicated where hypertriglyceridemia is the abnormality of most concern.

It is not always possible to predict from the lipoprotein type or other factors which patients will exhibit favorable results. Lipid levels should be periodically assessed. Small or transient changes in high density lipoprotein cholesterol may be due to inaccuracies in the method of determination. Substantial changes are sometimes seen with diet.

The effect of probucol-induced reduction of serum cholesterol or triglyceride levels or alteration of HDL-cholesterol levels on morbidity or mortality due to coronary heart disease has not yet been established. Several years may be required before ongoing long-term investigations will resolve this question.

CONTRAINDICATIONS: (See also PRECAUTIONS.) Lorelco is contraindicated in patients who are known to have a hypersensitivity to it.

WARNINGS: SERIOUS ANIMAL TOXICITY HAS BEEN ENCOUNTERED WITH PROBUCOL IN RHESUS MONKEYS FED AN ATHEROGENIC DIET AND IN BEAGLE DOGS. (SEE ANIMAL PHARMACOLOGY AND TOXICOLOGY SECTION.)

Although Q-T prolongation can occur in patients on probucol, the arrhythmias observed in monkeys fed large doses of probucol added to an atherogenic diet have not been reported in man; nevertheless, the following precautions are deemed prudent:

1. At the start of treatment with Lorelco and throughout the treatment period, patients should be advised to adhere to a low cholesterol, low fat diet.
2. As part of an overall evaluation, a baseline, six month, and one year repeat ECG tracing should be considered. If marked prolongation of the Q-T interval (after correction for rate) occurs, the possible benefits and risks should be carefully considered before making the decision to continue the probucol administration.

Lorelco should not be used in patients with evidence of recent or progressive myocardial damage or findings suggestive of ventricular arrhythmias.

No instances of increase in ectopy attributed to Lorelco have been reported. However, patients with unexplained syncope while on Lorelco should have ECG surveillance.

PRECAUTIONS

General: Because Lorelco is intended for long-term administration, adequate baseline studies should be performed to determine that the patient has elevated serum cholesterol levels. Serum lipid levels should be determined before treatment and repeated during the first few months of treatment and periodically thereafter. A favorable trend in cholesterol reduction should be evident during the first three to four months of administration of Lorelco. Probucol lowers serum total and LDL cholesterol, and also lowers HDL-cholesterol in many patients with elevated LDL-cholesterol. Epidemiologic studies within hypercholesterolemic populations have shown that serum HDL-cholesterol is an independent, inversely correlated, risk factor for coronary heart disease (see CLINICAL PHARMACOLOGY). Animal or human studies which could confirm or deny the hypothesis that drug induced alteration in HDL-cholesterol affects cardiovascular risk have not been carried out. It is not known whether probucol-induced reduction of serum HDL-cholesterol will affect cardiovascular risk since no long-term, controlled clinical trials of probucol for the prevention of coronary heart disease, similar to the LRC-CPPT (See CLINICAL STUDIES), have been performed. The probable benefits obtained from LDL-cholesterol reduction must be weighed against the possible risk of a reduction in HDL-cholesterol when assessing the response of each patient receiving Lorelco treatment. If satisfactory lipid alteration is not achieved, the drug should be discontinued.

Information for Patients: The patient should be instructed to adhere to a prudent diet. Females should be cautioned against becoming pregnant for at least six months after discontinuing Lorelco and should not breast feed their infants during therapy with Lorelco.

Laboratory Tests: The physician should schedule periodic blood lipid determinations and should consider periodic electrocardiograms. (See WARNINGS.)

Elevations of the serum transaminases (glutamic-oxalacetic and glutamic-pyruvic), bilirubin, alkaline phosphatase, creatine phosphokinase, uric acid, blood urea nitrogen and blood glucose above the normal range were observed on one or more occasions in various patients treated with Lorelco. Most often these were transient and/or could have been related to the patient's clinical state or other modes of therapy. Although the basis for the relationship between probucol and these abnormalities is not firm, the possibility that some of these are drug-related cannot be excluded. In the controlled trials, the incidence of abnormal laboratory values was no higher in the patients treated with probucol than in the patients who received placebo. If abnormal laboratory tests persist or worsen, if clinical signs consistent with the abnormal laboratory tests develop, or if systemic manifestations occur, probucol should be discontinued.

Drug Interactions: The addition of clofibrate to probucol is not recommended since the lowering effect on mean serum levels of either LDL or total cholesterol is generally not significantly additive and, in some patients, there may be a pronounced lowering of HDL-cholesterol. Neither oral hypoglycemic agents nor oral anticoagulants alter the effect of Lorelco on serum cholesterol. The dosage of these agents is not usually modified when given with Lorelco. Monkeys fed a high fat, high cholesterol diet admixed with probucol exhibited serious toxicity. The toxicity observed in monkeys has not been reported in man. (See WARNINGS and ANIMAL PHARMACOLOGY AND TOXICOLOGY sections.)

Carcinogenesis, Mutagenesis, Impairment of Fertility
In chronic studies of two years duration in rats, no toxicity or carcinogenicity was observed. These results are consistent with the lack of any adverse effect on fertility and the negative findings in tests for mutagenic activity in rats.

Pregnancy
Teratogenic Effects
Pregnancy—Category B: Reproduction studies have been performed in rats and rabbits at doses up to 50 times the human dose, and have revealed no evidence of impaired fertility or harm to the fetus due to probucol. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed. Furthermore, if a patient wishes to become pregnant, it is recommended that the drug be withdrawn and birth control procedures be used for at least six months because of persistence of the drug in the body for prolonged periods. (See CLINICAL PHARMACOLOGY.)

Labor and Delivery: The effect of Lorelco on human labor and delivery is unknown.

Nursing Mothers: It is not known whether this drug is secreted in human milk, but it is likely to be since such excretion has been shown in animals. It is recommended that nursing not be undertaken while a patient is on Lorelco.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Gastrointestinal
diarrhea or loose stools, flatulence, abdominal pain, nausea, vomiting, indigestion, gastrointestinal bleeding

Cardiovascular
prolongation of the Q-T interval on ECG

Neurologic
headache, dizziness, paresthesias, insomnia, tinnitus, peripheral neuritis

Hematologic
eosinophilia, low hemoglobin and/or hematocrit, thrombocytopenia

Dermatologic
rash, pruritus, ecchymosis, petechiae, hyperhidrosis, fetid sweat

Genitourinary
impotency, nocturia

Ophthalmic
conjunctivitis, tearing, blurred vision

Endocrine
enlargement of multinodular goiter

Idiosyncrasies
An idiosyncratic reaction observed with initiation of therapy and characterized by dizziness, palpitations, syncope, nausea, vomiting and chest pain has been observed.

Other
diminished sense of taste and smell, anorexia, angioneurotic edema

DRUG ABUSE AND DEPENDENCE: No evidence of abuse potential has been associated with Lorelco, nor is there evidence of psychological or physical dependence in humans.

OVERDOSAGE: There is a single report of a 15 kg, three-year-old male child who ingested 5 gm of probucol. Emesis was induced by ipecac. The child remained well, apart from a brief episode of loose stools and flatulence. No specific information is available on the treatment of overdosage with Lorelco and no specific antidote is available. Probucol is not dialyzable. Treatment is symptomatic and supportive. Probucol has shown no identifiable acute toxicity in mice and rats. In these animals the LD_{50} (oral) is in excess of 5 gm/kg of body weight.

DOSAGE AND ADMINISTRATION: For adult use only. The recommended and maximal dose is 500 mg (two tablets of 250 mg each) twice daily with the morning and evening meals.

HOW SUPPLIED: Each white film-coated tablet contains 250 mg probucol and is imprinted with the DOW diamond trademark over the code number 51, or LORELCO 250.
Bottles of 120 tablets, a 30-day supply for one patient (NDC 0068-0051-52)

Keep well closed. Store in a dry place. Avoid excessive heat. Dispense in well closed light-resistant container with child-resistant closure.

ANIMAL PHARMACOLOGY AND TOXICOLOGY: In rhesus monkeys administration of probucol in diets containing unusually high amounts of cholesterol and saturated fat resulted in the death of four of eight animals after several weeks. Premonitory syncope was frequently observed and was associated with a pronounced prolongation of the Q-T intervals (30 to 50 percent longer than that observed in untreated monkeys). Serum levels of probucol greater than 20 mcg/ml were generally associated with some prolongation in the Q-T interval in the cholesterol-fed monkey. A 75 msec or greater increase in Q-T interval from control values was usually seen at 40 mcg/ml and above. Blood levels in humans receiving probucol average approximately 20 mcg/ml and not uncommonly reach levels of 40 mcg/ml and higher. Rhesus monkeys fed normal (low fat) chow and receiving probucol three to thirty times the human dose equivalent achieved blood levels only one-third those of many human subjects. No adverse effects were detected in these monkeys over an eight-year period of continuous drug administration. In another study in rhesus monkeys, an atherogenic diet was fed for two years and daily treatment with probucol, separated in time from the atherogenic meal, was carried out during the second year. Serum probucol levels ranged 20 to 50 mcg/ml in five of ten monkeys, and less in the remaining animals. Marked prolongation of the $Q\text{-}T_c$ interval in the electrocardiogram or syncopal behavior was never observed over the entire one-year treatment period. Regression of gross aortic lesions comparable to that observed in a parallel group of monkeys receiving cholestyramine was seen in animals receiving probucol. It should be emphasized that both HDL-cholesterol and LDL-cholesterol were markedly reduced in this regression study. During the performance of a two-year chronic study involving 32 probucol-treated dogs (beagles) there were 12 fatalities. Subsequent experiments have indicated that probucol sensitizes the canine myocardium to epinephrine, resulting in ventricular fibrillation in many dogs. Among the animal species in which probucol has been studied, the dog is peculiar with respect to the phenomenon of sudden death due to the sensitization of the myocardium to epinephrine. In contrast to findings in the dog, injections of epinephrine to probucol-treated monkeys did not induce ventricular fibrillation.

In other studies, monkeys were given probucol either before and after, or only after myocardial infarction induced by coronary artery ligation. In these studies there was no difference between probucol- and placebo-treated groups with respect to either survival or detailed blind quantitation of myocardial changes (gross and histopathologic).

Probucol has shown no identifiable toxicity in mice and rats. In these animals the LD_{50} (oral) is in excess of five gm/kg of body weight. In chronic studies of two-year duration in rats, no toxicity or carcinogenicity was observed.

From studies in rats, dogs and monkeys, it is known that probucol accumulates slowly in adipose tissue. Approximately 90 percent of probucol administered orally is unabsorbed. For that which is absorbed, the biliary tract is the major pathway for clearance from the body and very little is excreted by way of the kidneys.

Myocardial injury was produced in various groups of rats by one of the following procedures: aortic coarctation, coronary ligation, or cobalt or isoproterenol injection. After probucol administration, no deleterious effects related to treatment occurred as measured by survival and microscopic examination of myocardial damage.

Probucol was administered to minipigs beginning ten days before ligation of coronary artery and continued for 60 days post surgery. Challenge with epinephrine at the end of 60 days failed to induce ventricular fibrillation in any of the coronary-ligated, probucol-treated minipigs.

CLINICAL STUDIES: In a multicenter, randomized, double-blind study, the LRC-CPPT[2], hypercholesterolemic patients treated with an oral bile acid sequestrant (cholestyramine) and a cholesterol lowering diet experienced average total and low-density lipoprotein cholesterol reductions greater than those obtained in the placebo group treated with diet alone. The cumulative seven-year incidence of the primary end point—combined incidence of definite CHD death and/or definite nonfatal myocardial infarction—was 7% in the cholestyramine group and 8.6% in the placebo group. This was a 19% reduction in risk (P less than 0.05, single-tail test) of the primary end point reflecting a 24% reduction in definite CHD death and a 19% reduction in nonfatal myocardial infarction.

The subjects included in the study were middle-aged men (35-59 years old) with serum cholesterol levels at least 265 mg/dl and no previous history of heart disease. It is not clear to what extent these findings can be extrapolated to other segments of the hypercholesterolemic population not studied.

The bile acid sequestrant, cholestyramine was used in the above trial. Caution should be exercised in extrapolating these results to probucol since it differs from cholestyramine with regard to its mode of action, spectrum of cholesterol-lowering potency, effect on HDL-cholesterol and possible toxicity. The effect of probucol-induced reduction of serum cholesterol levels on morbidity or mortality due to coronary heart disease has not yet been established. Several years may be required before ongoing long-term investigations will resolve this question.

Merrell Dow

Effect of Increasing Heart Rate on Left Ventricular Performance in Patients with Normal Cardiac Function

SAUL SCHAEFER, MD, ANNE L. TAYLOR, MD, HOWARD R. LEE, MD, ELAINE H. NIGGEMANN, MD, BENJAMIN D. LEVINE, MD, JEFFREY J. POPMA, MD, JERE H. MITCHELL, MD, and L. DAVID HILLIS, MD

The influence of an increase in heart rate on left ventricular (LV) contractile performance was assessed in patients with normal LV function. In 19 patients (3 men, 16 women) ages 55 ± 9 years (mean ± standard deviation) with normal global and segmental LV function and normal coronary arteries, LV dP/dt max was measured at baseline heart rate and during atrial pacing at baseline +5, baseline +25 and baseline +45 beats/min. In 10 of the patients, intravascular volume was not altered during pacing and, as a result, echocardiographically measured LV end-diastolic dimension decreased (5.4 ± 0.4 at baseline vs 4.9 ± 0.5 cm at baseline +45 beats/min, p <0.05). In these patients, LV dP/dt max increased modestly (1,571 ± 237 at baseline vs 1,760 ± 199 mm Hg/s at baseline +45 beats/min, p <0.05). In the other 9 patients, intravascular volume was expanded rapidly (by saline infusion) during pacing and, as a result, LV end-diastolic dimension was held constant (5.2 ± 0.6 at baseline vs 5.1 ± 0.6 cm at baseline +45 beats/min, difference not significant). In these patients, LV dP/dt max increased substantially with pacing (1,505 ± 228 at baseline vs 2,050 ± 258 mm Hg/s at baseline +45 beats/min, p <0.05). Thus, an increase in heart rate induces a modest increase in LV dP/dt max in patients in whom LV preload (as reflected by end-diastolic dimension) is allowed to decrease; in contrast, it causes a marked increase in LV dP/dt max in those in whom LV preload is maintained constant.

(Am J Cardiol 1988;61:617–620)

The strength of contraction of cardiac muscle is augmented when the rate of stimulation is increased.[1] This is true in isolated papillary muscle,[2,3] segments of ventricular myocardium,[4–6] isovolumically contracting ventricle[7–10] and the pumping heart of the anesthetized dog.[11,12] In the conscious dog, a pacing-induced increase in heart rate has been shown to cause a slight decrease[13] or a modest increase[14] in the maximal rate of left ventricular (LV) pressure rise (dP/dt max), a measure of ventricular contractility. During atrial pacing, LV end-diastolic volume declines; as a result, the positive inotropic effect of an increase in heart rate may be offset by a decrease in LV diastolic filling (preload). In fact, when LV preload is held constant during pacing (by the rapid infusion of saline), LV dP/dt max increases modestly (by an average of 14%) instead of decreasing (by an average of 6%).[13]

Previous studies in patients with coronary artery disease[15] or atrial septal defect[16] have yielded similar results, demonstrating that an increase in heart rate (caused by atrial pacing or atropine) induces only a modest increase in LV dP/dt max. As in the aforementioned canine studies, the improvement in LV performance caused by an increase in heart rate may be offset by a decrease in LV diastolic filling. No previously published study has examined the influence of an increase in heart rate on LV performance in patients with normal cardiac function or the magnitude of a pacing-induced increase in LV dP/dt max when

† $p < 0.05$ compared with baseline and baseline +5 bpm.

diastolic filling is held constant by a rapid expansion of intravascular volume. The present study was performed to address these issues.

Methods

Patient population: Nineteen patients (3 men, 16 women), aged 33 to 68 years, referred for catheterization for the evaluation of chest pain were studied after they gave written informed consent. Beta-adrenergic blocking agents, calcium antagonists and long-acting nitrates were discontinued 24 hours before catheterization. Patients were studied in the fasting state after premedication with 10 mg oral diazepam. In each patient, left ventriculography demonstrated normal global and segmental LV function, and selective coronary arteriography demonstrated normal coronary arteries.

Experimental protocol: Thirty minutes after the completion of selective coronary arteriography, a bipolar pacing catheter was positioned in the high right atrium, and a micromanameter-tipped pigtail catheter (Millar Instruments) was placed in the left ventricle; the first derivative of LV pressure (dP/dt max) was then recorded. Systemic arterial pressure was measured continuously via a brachial or femoral arterial cannula. LV end-diastolic dimension was quantitated with targeted M-mode echocardiography using a Hewlett-Packard phased array 2-dimensional echocardiogram (model 77020 AC) with a 2.5-mHz transducer. Images were recorded on videotape for machine caliper measurement of end-diastolic dimension during saline infusion and on paper at 50 mm/s for later analysis. End-diastolic dimension was measured for 5 cardiac cycles at each heart rate and the values averaged. The measurements were taken at the tips of the papillary muscles, and these internal landmarks were used to ensure that measurements were performed consistently at the same anatomic location. End-diastole was defined at the peak of the R wave on a simultaneously recorded electrocardiogram.

LV end-diastolic dimension, systemic arterial pressure and dP/dt max were recorded at the patient's baseline heart rate. Then, atrial pacing was initiated at 5 beats/min above baseline rate. After 2 minutes of pacing, LV dimension, arterial pressure and dP/dt max were again recorded. These same variables were measured after 2 minutes of pacing at both 25 and 45 beats/min above the baseline rate to a maximal rate of 140 beats/min.

Before the experimental protocol was performed, each patient was randomly assigned to 1 of 2 groups. Group A received no saline infusion (n = 10); group B received saline infusion during pacing (n = 9). In the latter group, normal saline was rapidly administered (through a catheter in the femoral vein) to maintain a constant LV end-diastolic dimension.

Data analysis: Results are reported as mean ± 1 standard deviation. For groups A and B, the data for LV end-diastolic dimension, systolic arterial pressure and dP/dt max during the 4 heart rates (baseline, baseline +5 beats/min, baseline +25 beats/min, baseline +45 beats/min) were assessed with a repeated measures analysis of variance. The 2 groups were compared with Student *t* test.[17] For all analyses, a p value <0.05 was considered significant.

Results

Group A—Atrial pacing without saline infusion: For these 10 patients, LV ejection fraction averaged 0.71 ± 0.10 (range 0.51 to 0.85). As heart rate increased with atrial pacing, there was a stepwise decrease in LV end-diastolic dimension and a modest increase in dP/dt max (Table I). The individual responses of dP/dt max are shown in Figure 1. Systemic arterial pressure did not change significantly during atrial pacing. For these 10 individuals, the increase in LV dP/dt max with atrial pacing averaged 4.2 ± 5.1 (range −3.6 to +10.3) mm Hg/s/beat. From baseline to baseline +45 beats/min, dP/dt max increased 13 ± 16%.

Group B—Atrial pacing with saline infusion: For these 9 individuals, LV ejection fraction was 0.69 ± 0.10 (range 0.51 to 0.84). As heart rate increased with atrial pacing, LV end-diastolic dimension was main-

tained (by saline administration); systemic arterial pressure did not change significantly; and LV dP/dt max increased markedly (Table I, Figure 1). The increase in dP/dt max with atrial pacing averaged 12.3 ± 4.4 (range +6.2 to +19.7) mm Hg/s/beat, a significantly greater increase than that found in group A ($p = 0.002$). From baseline to baseline +45 beats/min dP/dt max increased 36 ± 17%, a greater increase than that noted in group A ($p = 0.007$).

Discussion

Previous studies in the conscious dog have shown that an increase in heart rate induces only a modest change in LV contractile performance, as reflected by dP/dt max. In 14 animals, Mahler et al[14] demonstrated a modest (16%) increase in LV dP/dt max as heart rate rose from 90 to 158 beast/min. In 10 animals, Higgins et al[13] measured LV dP/dt max and end-diastolic dimension during incremental atrial pacing. As heart rate increased, end-diastolic dimension decreased, and dP/dt max declined slightly (average 6%). Since the positive inotropic effect of a pacing-induced increase in heart rate may be offset by a decrease in LV diastolic filling (preload), these investigators[13] measured LV dP/dt max during incremental atrial pacing as LV diastolic dimension was held constant by the rapid infusion of saline. In these animals, dP/dt max increased by an average of 14%. In short, a pacing-induced increase in heart rate in the conscious dog appears to exert only a modest inotropic influence, even when LV preload is maintained by the rapid expansion of intravascular volume.

The inotropic effect of an increase in heart rate in man has not been well characterized. Gleason and Braunwald[16] measured LV dP/dt max in 3 patients with atrial septal defect before and after atropine. In these subjects, dP/dt max increased by 8.2 ± 4.7 mm Hg/s/beat (individual values, 11.2, 10.7 and 2.8). O'Brien et al[15] measured LV dP/dt max before and during atrial pacing in 7 patients with coronary artery disease; dP/dt max increased by 7.1 ± 13.6 (range −11.4 to +32.2) mm Hg/s/beat. In both of these studies, LV end-diastolic volume presumably fell as heart rate increased,[18] and this decrease in preload may have offset at least some of the positive inotropic effect of an increase in heart rate.

In the present study, we measured LV dP/dt max, end-diastolic dimension and systemic arterial pressure during incremental atrial pacing in 19 patients with normal LV function and coronary arteries. During atrial pacing alone, end-diastolic dimension decreased, systemic arterial pressure was unchanged and dP/dt max increased modestly (average increase 4.2 ± 5.1 mm Hg/s/beat, 13 ± 16%) (Table I, Figure 1). In contrast, in the 9 patients in whom saline was rapidly infused during atrial pacing to maintain a constant end-diastolic dimension, dP/dt max increased substantially (average increase 12.3 ± 4.4 mm Hg/s/beat, 36 ± 17%). The p values were 0.002 and 0.007, respectively, in comparison to those in whom pacing was performed without volume infusion) (Table I, Figure 1).

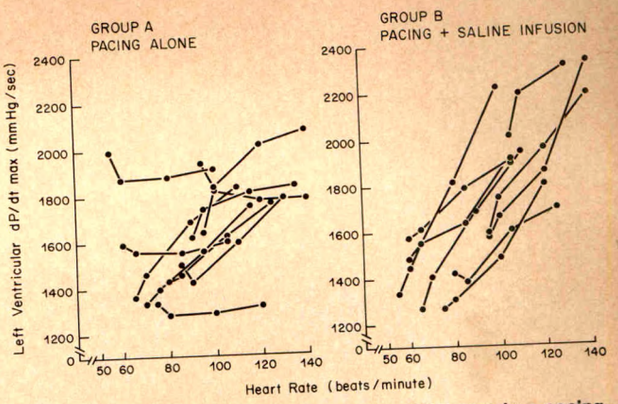

FIGURE 1. The response of left ventricular dP/dt max to a pacing-induced increase in heart rate in patients without (*left*) or with (*right*) the simultaneous infusion of saline (to maintain a constant left ventricular end-diastolic dimension). Each line represents the data from 1 patient. Left ventricular dP/dt max increased markedly during pacing-induced tachycardia in those given saline (*right*).

LV dP/dt max, a widely used index of myocardial contractility, is influenced by several factors.[12] An increase in heart rate, systemic arterial pressure or LV end-diastolic volume causes an increase in dP/dt max, whereas a decrease in these variables induces a decrease in dP/dt max.[16,19–21] In the present study, atrial pacing did not significantly alter systemic arterial pressure in those not given saline (group A) or those to whom saline was administered (group B) (Table 1). In those given saline, LV end-diastolic volume was held constant during incremental atrial pacing. Therefore, the observed increase in LV dP/dt max during pacing was due solely to the increase in heart rate.

During supine or upright exercise, LV end-diastolic volume and heart rate increase, and cardiac output rises.[22] Since LV preload is maintained or increases, the positive inotropic influence of exercise-induced tachycardia may contribute substantiallly to enhanced LV performance. Thus, the positive inotropic effect of an increase in heart rate is considerable if LV preload is maintained.

Intrinsic Left Ventricular Contractility in Normal Subjects

MARVIN W. KRONENBERG, MD, JACK P. UETRECHT, MD, PhD, WILLIAM D. DUPONT, PhD, MICHAEL H. DAVIS, MD, BRIAN K. PHELAN, MD, and GOTTLIEB C. FRIESINGER, MD

The influence of autonomic tone on left ventricular (LV) contractility, along with the range of normal values and the effects of exercise on contractile state, were studied in 12 normal volunteers. Serial reproducibility was examined in a subgroup of 6. LV contractility was estimated by the LV peak-systolic pressure to end-systolic volume relation (pressure-volume relation), and the ratio of peak-systolic pressure to end-systolic volume (pressure/volume ratio). The cuff blood pressure and radionuclide ventriculogram were recorded at rest, during exercise and during pharmacologic pressure-afterloading with phenylephrine, before and after vagal and β-adrenergic "blockade." Both the pressure/volume ratio and ejection fraction increased during the stimulus of exercise (both $p \leq 0.008$). After blockade, the pressure-volume relations were highly linear ($r = 0.95 \pm 0.05$ [standard deviation], $n = 12$), and there was no systematic difference in their slopes induced by blockade. The serial studies of pressure-volume relations showed no significant differences. The results demonstrated that vagal and sympathetic tone were not important in the support of LV contractility in normal subjects at rest, and that the pressure-volume relation and pressure/volume ratio are reproducible between studies. Also, the findings confirmed that both the pressure/volume ratio and the ejection fraction were sensitive to exercise-induced changes in contractility. This demonstration of intrinsic LV contractility in normal subjects, plus the reproducibility of the measurements, supports the feasibility of serial study of LV contractility.

(Am J Cardiol 1988;61:621–627)

The left ventricular (LV) end-systolic pressure-volume relation and variations have been employed as estimates of LV contractility.[1–12] However, there are few data to define the normal range of pressure-volume relations,[6,7,9–12] reproducibility[13,14] or effects of autonomic tone.[12,15] Autonomic tone might be important in setting the baseline ("intrinsic") contractile state, because the heart is richly innervated. Previously, Jose and Taylor[16] studied "intrinsic cardiac function" using atropine and propranolol to produce "autonomic blockade." In the present study, we employed the systolic pressure-volume concept and radionuclide ventriculography to evaluate "intrinsic LV contractility" in normal subjects at rest, during exercise and during autonomic blockade to assess the influence of autonomic tone. The reproducibility of the data was investigated.

Methods

Population and protocol: We studied 14 normal volunteers. They were untrained, asymptomatic adults (9 men, 5 women), ages 33 ± 12 years (standard deviation), range 21 to 69. Each had a normal physical examination, took no medications and gave written informed consent on forms approved by our institutional review board. Serial studies were performed in 9.

Intravenous cannulae were inserted in right and left forearm veins for blood sampling and drug infusion, respectively. The subjects lay supine and were studied while fasting. Radionuclide ventriculograms were collected to estimate LV volume (see later) and auscultatory blood pressure was measured simultaneously using an 8-stage protocol (Figure 1). Data were collected at rest (stage 1), during supine bicycle ergometer exercise (stage 2) and after a recovery period of 20 to 30 minutes following exercise (stage 3). Then, the systolic blood pressure was increased in steps by a phenylephrine infusion (stages 4 and 5). After discontinuing phenylephrine, atropine and propranolol were infused intravenously to produce vagal and β-adrenergic "blockade." Loading doses were followed by maintenance infusions. Data were reacquired when the systolic pressure was stable (stage 6). Then, the phenylephrine infusion was repeated to achieve 2 pressure increments and measurements were repeated (stages 7 and 8). The protocol required 3 hours, with 45 minutes for stages 6 through 8.

Imaging: Red blood cells were labeled in vivo[17] using 25 mCi technetium-99m pertechnetate. Electrocardiographic R-wave gated images of the cardiac blood pool in the left anterior oblique projection were collected by a PhoGamma IV scintillation camera (Siemens) using a low-energy all-purpose collimator and a symmetrical 20% window. They were stored by a PDP 11/40 computer (Digital Equipment), using a 64 × 64 image matrix, 30 ms per frame, 20 frames per cardiac cycle and variable hardware zoom for magnification. Images were collected for 2 million counts at rest (usually 5 minutes) and for 3 minutes on exercise. For estimating LV volume, with each image a 5-ml blood sample was drawn intro a heparinized syringe, transferred to a Petri dish using a pipette with 0.5% error at full scale (Oxford Macro-Set, Sherwood Medical), placed on the collimator and counted for 5 minutes afterwards.

Blood pressure was assessed once a minute during imaging with an ameroid cuff sphygmomanometer.

Drug infusion: Phenylephrine was infused with a calibrated pump (Harvard). After the initial rate of 0.2 μg/kg/min, the rate was increased to achieve an approximate 20 mm Hg increment in systolic pressure. Then, the radionuclide ventriculogram was repeated and the rate increased for a similar pressure increment before another image. This sequence was repeated after vagal and β-adrenergic "blockade."[16] For this, atropine (0.2 mg/ml) was infused over 10 to 15 minutes to a total loading dose of 0.04 mg/kg. The maintenance dose was 0.2 μg/kg/min. Propranolol was infused simultaneously, totalling 0.2 mg/kg. The maintenance dose was 1.1 μg/kg/min.

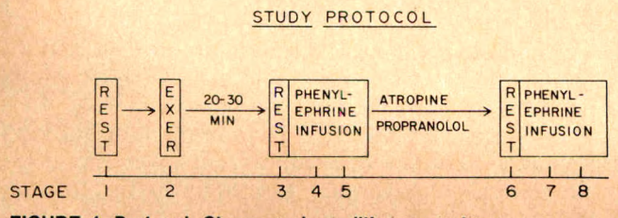

FIGURE 1. Protocol. Stages and conditions are shown.

Exercise protocol: Exercise was performed by pedaling a bicycle ergometer (Collins), supine at 60 rpm, beginning at 25 watts and increasing over 2 to 3 minutes to an individualized maximal load for a 3-minute exercise image.

Serial studies: Two weeks to 3 months later, a second study was performed in 9 subjects following an identical protocol. All subjects able to return were studied without reference to their initial evaluation.

Radionuclide ventriculography: We evaluated this method for estimating the LV ejection fraction and volume using software of our design.[18] Among 18 patients, the correlation for ejection fraction between radionuclide and contrast ventriculography was 0.93 ($p < 0.001$).[19] In 9 other patients, the correlation between radionuclide and contrast LV volume was 0.94 ($n = 18$, $p < 0.001$) (combining end-diastole and end-systole), where contrast = 3.16 + 4.54 (radionuclide) using the method of Dehmer et al.[19]

Reproducibility: In a wide variety of 50 radionuclide ventriculograms, intraobserver variability for end-systolic volume (ml) in duplicate trials was <2% (difference not significant) with close correlation ($r = 0.99$, $p < 0.001$; trial 1 = 0.67 + 0.97 × trial 2). In 47 studies analyzed by 2 observers independently, interobserver variability for end-systolic volume was 3% (difference not significant) with close correlation ($r = 0.99$, $p < 0.001$; observer 1 = −1.54 + 1.05 × observer 2). There were equally close intra- and interobserver results for end-diastolic volume and ejection fraction with correlation coefficients >0.98.

Blood pressure: In 9 consecutive catheterized patients there was close correlation between the systolic blood pressure (mm Hg) by cuff and in the ascending aorta (cuff = −1.68 + 1.03 × aortic) ($r = 0.991$, $p < 0.001$).

Data analysis: The 5 systolic and diastolic pressures during each radionuclide ventriculogram were averaged.

Radionuclide ventriculograms were analyzed in duplicate for end-diastolic volume, end-systolic volume and ejection fraction.

Pressure-volume relations were evaluated by 2 methods. First, the relation of peak-systolic pressure to LV end-systolic volume (pressure-volume relation) was assessed before and during phenylephrine infusions, both before and after autonomic blockade (stages 3 to 5 and 6 to 8). The pressure-volume data were graphed and examined by linear regression analysis. The slope, the standard error of the slope estimate and the extrapolated value of end-systolic volume at a systolic pressure of zero were tabulated. Second, the ratio of peak-systolic pressure to LV end-systolic volume (pressure/volume ratio) was calculated at rest and during exercise.

Repeated measurements and duplicate data were examined by analysis of variance, paired t tests and linear regression, as appropriate. Statistically significant differences were defined as $p < 0.05$.

Results

Fourteen subjects had 1 study and 9 subjects had 2. Studies were excluded only for inadequate definition of the left ventricle, artifacts in blood sample counts or inadequate exercise electrocardiographic gating. For study 1, there were technically excellent rest-exercise pressure/volume ratios for 13 subjects and pressure-volume relations for 12. For study 2, there were pressure/volume ratios and pressure-volume relations for 6.

Rest-exercise results: In study 1 the pressure/volume ratio increased from 3.6 ± 2.7 mm Hg/ml "units" at rest to 7.9 ± 3.5 during exercise (n = 13, p <0.001) (Figure 2A, Table I). We compared the reproducibility of the pressure/volume ratios of studies 1 and 2 (Figure 2B). There were no significant differences in the group data of pressure/volume ratios at rest or during exercise, but for individuals the ratios differed by <3.2 units at rest and <2.5 units during exercise.

Pressure-volume relations: The average increment in systolic pressure between stages was 22 mm Hg. Before blockade, the average heart rate slowed as the pressure increased, from 80 at stage 3 to 56 at stage 4 and to 49 at stage 5. After blockade, the heart rate averaged 109 during stage 6 and 114 during stage 8. Systolic blood pressure was 153 ± 12 mm Hg in stage 5 and 159 ± 12 mm Hg in stage 8 (p = 0.04). The phenylephrine infusion rate averaged 1.3 μg/kg/min in stage 4 and 2.2 in stage 5, but only 0.8 in stage 7 (p <0.001 vs stage 4) and 1.1 in stage 8 (p <0.002 vs stage 5). The plasma propranolol concentration was measured 8 times in 7 subjects at the beginning and end of the maintenance infusion (45 minutes). The initial level was 80 ± 25 ng/ml and the final level 77 ± 18 ng/ml (difference not significant).

Figure 3 illustrates 2 general patterns of pressure-volume relations before and after blockade. In panel A the relations were linear before and after blockade (subject 8), but panel B shows a marked leftward shift of the pressure-volume relation before blockade (subject 11) at the higher dose of phenylephrine. Figure 4 displays the pressure-volume relations for all 18 studies in the 12 subjects, before and after blockade. We inspected these curves for linearity, after excluding 2 (subject 1, study 1, preblockade; subject 4, study 1, postblockade). Of these 2, the first had a very small pressure change and the second had only 2 points for analysis since phenylephrine was discontinued because of headache. Of the remaining 16, before blockade, 7 were linear but 9 showed a leftward shift at the highest pressure. After blockade, only 2 showed such a leftward shift. The difference in linearity before and after blockade was significant (p = 0.02).

Table II lists the pressure-volume relations for studies 1 and 2. The pressure-volume relations after blockade were estimated from stages 6 through 8. There were 3 data points for 11 of 12 subjects, and the r values of their pressure-volume slopes were linear, averaging 0.95 in study 1. Slopes before blockade were estimated from stages 3 and 4. This avoided the nonlinearity in stage 5, assumed to be due to β-adrenergic stimulation. In study 1, the slope before blockade was 2.2 ± 1.1 mm Hg/ml (n = 12); after blockade it had become 2.5 ± 1.6. These values were not significantly different. In that study, the extrapolated end-systolic volume for a systolic pressure of 0 averaged −30 ml before blockade and −28 ml after it. These values were not significantly different. In study 2, the extrapolated volume averaged −28 ml before blockade and −6 ml after (p = 0.051), approaching, but not achieving standard statistical significance.

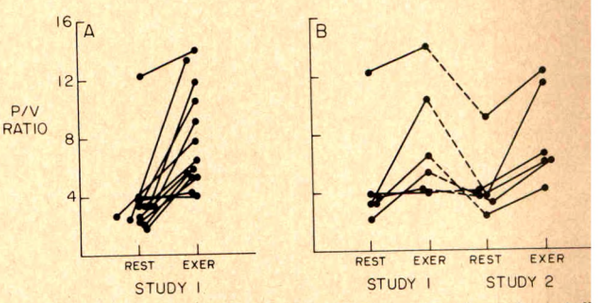

FIGURE 2. Pressure/volume ratio. *A*, the ratio of peak-systoli pressure to end-systolic volume increased on exercise. *B*, duplicat rest and exercise ratios were not significantly different in seri studies. The maximum difference in the exercise pressure/volum ratio was 2.5 units. P/V = pressure/volume.

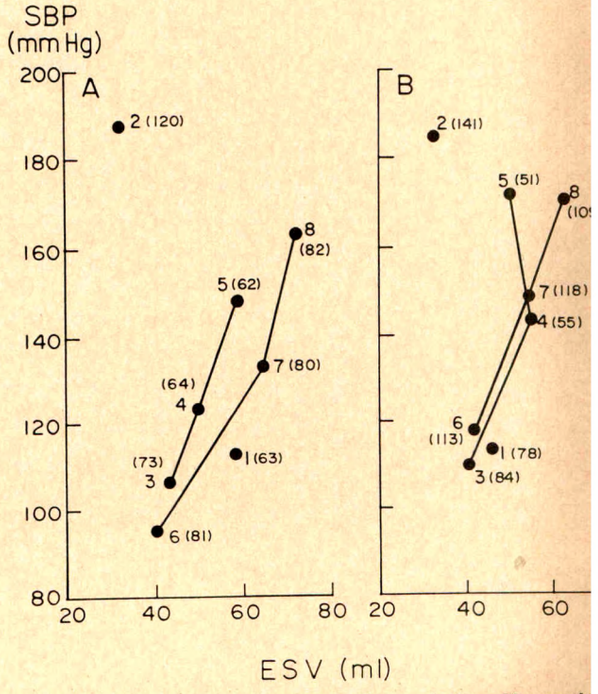

FIGURE 3. Two patterns of pressure-volume relations. The numb 1 through 8 denote stages in the protocol and the numbers parentheses represent heart rate. *A*, subject 8: the systolic pr sure-volume relation was linear before and after blockade. *B*, s ject 11: there was a marked leftward shift in the pressure-volu relation with a higher infusion rate of phenylephrine before au nomic blockade. The relation was more linear after blockade

M = slope of linear regression of end-systolic pressure-volume relations; r = Pearson correlation coefficient; SE = standard error of estimate; V_0 = ESV when SBP equals 0. Values were not significantly different by paired *t* tests.

Reproducibility of pressure-volume relations: Pressure and volume were reproducible after autonomic blockade in the group of 6 serial studies (Figure 5). The individual pressure-volume data were quite similar visually (Figure 4), and statistically (Table II). There were no significant differences in the pressure-volume slopes either before or after blockade, or in the volumes at zero-pressure. Also, the 95% confidence limits of the standard error of the slope estimates after blockade overlapped in every case.

Discussion

End-systolic pressure volume relations reflect LV contractility.[1–7,10–13] We examined peak systolic pressure to end-systolic volume relations to assess in normal volunteers the importance of autonomic tone, the effects of exercise and the reproducibility of the data. We found no significant effect of autonomic tone on systolic pressure-volume relations or on pressure/volume ratios; reproducibility was generally good. The pressure/volume ratio increased during exercise, reflecting increased contractility.

Pressure-volume relations and pressure/volume ratio: The slope of the LV end-systolic pressure-volume relation equals the end-systolic pressure divided by the difference of the end-systolic volume minus a correction factor (the volume at zero pressure, termed V_0).[2] Suga et al[1] and Sagawa et al[8] proposed the pressure/volume ratio as an estimate of contractility. This ratio may be considered as 1 related locus of the pressure-volume relation, but its absolute value differs from the slope value because of V_0.

In the isolated heart, LV volume is altered by a compliant balloon. There, the systolic pressure-volume relation is linear and the V_0 usually has a positive value.[2,20] However, V_0 has yet to be determined directly in vivo. We confirmed that systolic pressure-volume relations were linear, but the extrapolated V_0 was usually negative. This value has been reported both as positive[3,4,6,7,21] and negative.[5,21] Such extrapolation assumes linearity, but negative values imply nonlinearity below the operating range. Thus, extrapolation of V_0 may be invalid and greater reliance should be placed on actual pressure and volume measurements.

The pressure/volume ratio may change by altering pressure, volume, or both. An increase in pressure coupled to a decrease in volume is consistent with increased contractility, and this occurred during exercise in our study.

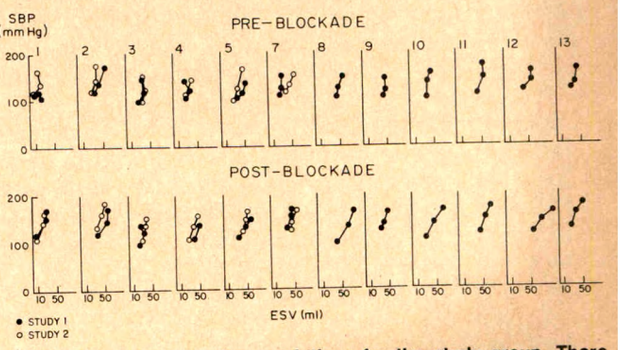

FIGURE 4. Pressure-volume relations for the study group. There was an overall similarity. Serial studies in 6 subjects were generally concordant. Data were more linear after autonomic blockade for reasons explained in the text. Numbers above graphs specify subjects as listed in tables.

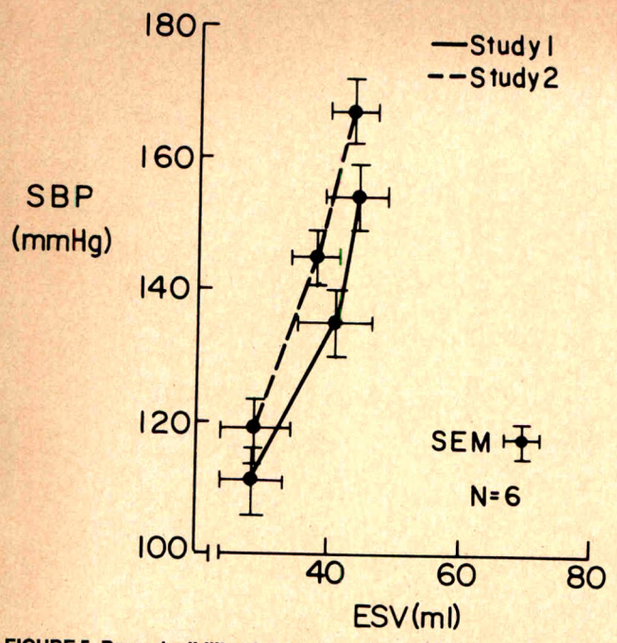

FIGURE 5. Reproducibility of pressure-volume relations. Stages 6 to 8 of studies 1 and 2 are shown. The mean pressure and volume were not significantly different.

Autonomic blockade: Whereas others have examined contractility in transplanted hearts (denervated),[12,22] the present study used a more direct approach by investigating the effects of autonomic tone on LV contractility and reproducibility in normal subjects. There was no difference in the slope of the pressure-volume relation before or after blockade after excluding stage 5, which was probably affected by phenylephrine's β-adrenergic effect.[23,24] Resting autonomic tone seems relatively unimportant for supporting normal LV contractility in dogs.[3] There are fewer data in normal humans. Borow et al found no differences between pressure-dimension relations in transplanted denervated hearts and in other normal subjects.[12] Crawford et al found that end-systolic dimension was unchanged before and after oral propranolol.[15] However, in heart failure,[16] cardiac output decreased after blockade but not in normal subjects. Thus, sympathetic drive may support contractility in heart failure, but not in the normal population.

Reproducibility: The duplicate, serial pressure-volume relations in 6 subjects were not significantly different. The greatest difference between duplicate pressure/volume ratios during exercise was 2.5 units and may represent the upper limit of normal variability.

Potential limitations included the volume and blood pressure methods, the effect of heart rate and drugs. The radionuclide method is affected by attenuation[25-27], but can quantitate volume,[3,19,25-27] small changes in volume,[27] pressure-volume loops[28] and pressure-volume relations.[27] Changes in the same subject should be assessed reliably, because attenuation should be constant.

Using 3 points per pressure-volume curve and peak systolic pressure might cause errors. Although there are problems in using 3 points to define linearity, other studies have proven this point.[1-3,5-8,10-14,20,21,27,29] Estimates of contractility by peak and end-systolic pressure are quite similar,[4,5,21,29] but the former has steeper slopes.

Tachycardia is a moderate, positive inotropic stimulus[22,30,31] and may decrease end-systolic volume.[22,28] In our study, the mean heart rate increased 29 beats from stage 3 to 6, but in 1 of our subjects a 40-beat increase did not affect pressure-volume relations in further studies (data not shown). Baroreceptor-mediated bradycardia (as before blockade) has not been studied, but when pacing stops, end-systolic volume[22] and end-systolic dimension[30] change minimally. Reflexes, hormonal background and coronary perfusion pressure might modify the effect of rate alone.[31] The available data favor our conclusion that vagal and β-adrenergic stimuli do not significantly alter normal LV contractility.

Phenylephrine has cardiac β-adrenergic effects[23,24] and our data confirm this in some subjects (Figures 3 and 4). Less phenylephrine was required to raise the blood pressure after blockade, probably by attenuating β-adrenergic vasodilation.[32] β-adrenergic blockade seems necessary before using phenylephrine. Although methoxamine might be as useful,[33] it also may affect contractility.[24,34,35]

Strategies for Increasing Early Adherence to and Long-Term Maintenance of Home-Based Exercise Training in Healthy Middle-Aged Men and Women

ABBY C. KING, PhD, C. BARR TAYLOR, MD, WILLIAM L. HASKELL, PhD, and ROBERT F. DEBUSK, MD

Two studies were undertaken to compare strategies for the adoption and maintenance of moderate-intensity, home-based exercise training. In the study of adoption, 52 men and women who had served for 6 months as controls for a study of moderate-intensity, home-based exercise training received 30 minutes of baseline instruction. They were then randomized to receive continuing instruction and support through 10 staff-initiated telephone contacts of 5 minutes each every 2 weeks, or to receive no telephone contacts. In subjects receiving telephone contacts, peak oxygen uptake increased significantly after 6 months, whereas no increase was observed in subjects receiving no staff support ($p < 0.05$). In the maintenance study, 51 men and women who had significantly increased their peak oxygen uptake by 6 months of moderate-intensity, home-based exercise training were randomized to undergo daily self-monitoring and receive adherence instructions, or undergo weekly self-monitoring only, during a second 6-month period of training. Subjects performing daily self-monitoring reported completing significantly more exercise training sessions during the 6 months of training than subjects performing weekly self-monitoring; functional capacity in both groups remained higher than before training ($p < 0.05$). Taken together, these studies suggest that brief baseline instruction followed by continuing telephone contact with staff can be used to help people adopt a moderate-intensity, home-based exercise training program that can be maintained by simple self-monitoring strategies.

(Am J Cardiol 1988;61:628–632)

Despite the known health benefits of regular physical activity,[1,2] most American adults continue to remain quite inactive.[3] This is particularly true for middle-aged and older men and women.[4,5] Factors influencing participation in physical activity include the type of activity, its intensity, frequency, and level of discomfort, convenience, perceived risk and enjoyment associated with it.[6] Surveys indicate that many people prefer moderate-intensity activities such as brisk walking as opposed to more vigorous activities,[3] and those they can perform individually rather than in a structured setting.[7] Significant increases in functional capacity have been achieved in healthy individuals[8,9] through home-based exercise training with medical supervision provided by telephone and mail contact. Studies show that home-based exercise training at low to moderate intensity (60 to 75% of the peak heart rate)[8] and moderate intensity (65 to 77% of the peak heart rate)[9] fits these preferences and significantly increases the functional capacity of healthy middle-aged persons.

The present study was designed to evaluate strategies for enhancing the adoption and maintenance of exercise training by healthy middle-aged participants in a 6-month randomized trial of home-based exercise training.[9] The level of adoption of exercise was evaluated over a 6-month period in subjects who had served as controls during the preceding 6 months of the randomized trial. The maintenance of exercise was evalu-

ated over a 6-month period in subjects who had undergone exercise training in the preceding 6 months of the randomized trial. Adoption and maintenance studies included 2 levels of intervention.

Adoption: One group of subjects in the adoption study received support and guidance through regularly scheduled phone contacts by project staff and 1 group received no such support and guidance.

Maintenance: One group in the maintenance study was instructed in daily self-monitoring of activity and 1 group was instructed in weekly self-monitoring.

Methods

Participants were 52 and 51 healthy men and women, ages 49 ± 6 and 47 ± 5, respectively, employed at Lockheed Missiles and Space Corporation in Sunnyvale, California. They had previously participated in a 6-month randomized, controlled trial to evaluate the physiologic effects of moderate-intensity, home-based exercise training.[10] Eligibility for the original trial included age 40 to 60, <25% overweight based on 1959 Metropolitan Life Insurance tables and absence of major musculoskeletal problems, overt cardiopulmonary disease or cardiac medications. At the end of the 6-month trial, the 52 control subjects and 51 training subjects completing Phase I were invited to participate in the Phase II trial (Figure 1).

Adoption study: The 26 men and 26 women participating in the adoption study received instructions for moderate-intensity, home-based exercise training similar to those provided to participants in the Phase I training study. Exercise training was at a heart rate 65% of that achieved during symptom-limited treadmill exercise testing plus 20 beats, 4 times per week and 30 minutes per session. Subjects were oriented to the home-based training program by the project staff in a 15-minute face-to-face session which followed participants' viewing of a 15-minute videotape on exercise training. Subjects used a portable heart rate monitor (Pacetron, Neuromedics) to assist them to remain within the prescribed training heart rate range. This monitor, which used electrodes strapped to the chest, emitted an audible tone when the heart rate was above or below the prescribed training range.

All participants were instructed in self-directed behavioral strategies that would aid them to exert better control over their exercise. These included relapse-prevention strategies[11,12] to limit the negative impact of missed sessions on subsequent adherence. They were taught to identify high-risk situations leading to breaks in their exercise regimen and to avoid or cope with such breaks. They were instructed in daily self-monitoring of exercise including the frequency and duration of exercise, ratings of perceived exertion during exercise using the Borg Scale[10] and of the enjoyment and convenience of the exercise sessions. These daily monitoring logs were mailed to the staff once each month.

The staff spoke on the phone with the 14 men and 15 women randomized to adoption-condition 1 to discuss the progress of their exercise program and to offer support and guidance (Table I). An average of 10 such telephone contacts averaging 5 minutes each was made within the 6-month training period.

The 12 men and 11 women randomized to adoption-condition 2 received the same instruction and follow-up as participants in condition 1, except that regular staff-initiated telephone contact was omitted (Table I). Participants in both conditions with >2 week overdue exercise logs received a reminder telephone call from a staff member.

Maintenance study: The 26 men and 25 women participating in the maintenance study received instructions for moderate-intensity home-based exercise training identical to those provided to participants in the adoption study. Self-monitoring was the principal strategy for maintaining adherence. The 13 men and 15 women randomized to condition 1 were instructed in daily monitoring of the frequency, duration, intensity and perceived enjoyment and convenience of their exercise sessions. They completed exercise logs which

TABLE III Peak Oxygen Uptake at Baseline, 6 Months and 12 Months for Adoption and Maintenance Studies

		Mean VO_2 Max (ml/kg/min)		
	n	Baseline	6 mo	12 mo
Adoption study				
Condition 1 (phone contacts)	27	30 ± 6	30 ± 6	32 ± 7*
Condition 2 (no phone contacts)	21	30 ± 5	30 ± 6	31 ± 6
Maintenance study				
Condition 1 (daily monitoring)	27	29 ± 6	33 ± 6	31 ± 6
Condition 2 (weekly monitoring)	20	30 ± 5	33 ± 6	32 ± 6

* Comparison between conditions 1 and 2, $p < 0.05$.
VO_2 = peak oxygen uptake.

were mailed to the staff each month. They also received a list of adherence tips and guidelines. The 13 men and 10 women randomized to maintenance condition 2 were instructed in weekly monitoring of the frequency, duration and intensity of their exercise sessions. These individuals completed exercise logs and returned them every 3 months (Table II).

Laboratory evaluation: The laboratory evaluation, conducted at baseline and 6 and 12 months afterwards, was identical for all participants. It included a symptom-limited treadmill exercise test with monitoring of blood pressure, electrocardiogram, rating of perceived exertion and measurement of oxygen consumption.[9]

Statistical analysis: Unpaired *t* tests were used to compare differences in the changes between groups. Paired-comparison *t* tests were used to compare differences within groups. Five percent 2-tailed *t* tests were used.

Results

Adoption study: Regarding self-reported adherence, the number of exercise sessions reported on the monthly exercise logs during the 6-month period was 12.4 ± 6 for condition 1 and 9.8 ± 8 for condition 2 (not significant). The duration of reported exercise sessions in conditions 1 and 2 was 32 ± 6 and 28 ± 10 minutes, respectively (not significant). There were no sex differences in either frequency or duration of exercise.

Changes in peak oxygen uptake: Twenty-seven of the 29 condition 1 participants (93%) and 21 of the 23 condition 2 participants (91%) returned for treadmill testing at the end of the 6-month adoption period (Figure 1). Values of peak oxygen uptake (VO_2 max) at 12 months were 8% and 2% higher than at 6 months in subjects of condition 1 and 2, respectively ($p < 0.05$) (Figure 2). The increase in VO_2 max was similar for men and women. Values of VO_2 max throughout Phases I and II of the study are shown in Table III.

Correlations between self-reported adherence and changes in peak oxygen uptake: The change in VO_2 max was significantly correlated with self-reported adherence to exercise training. Pearson product moment correlations were $r = 0.54$ for the number of exercise sessions per month ($p < 0.001$) and $r = 0.38$ for the average rating of perceived exertion per exercise session ($p < 0.002$). The number of sessions reported was significantly correlated with the rated enjoyment of the sessions ($r = 0.46$, $p < 0.01$) and with the rated convenience of exercise ($r = 0.40$, $p < 0.01$).

Maintenance study: Data on self-reported adherence showed that the number of reported exercise sessions per month during the 6-month period was 11.4 ± 6 for condition 1 subjects and 7.5 ± 6 for condition 2 subjects ($p < 0.01$). There was no sex difference in frequency or intensity of exercise. Mean duration of exercise sessions for condition 1 was 37 ± 9 minutes.

Changes in peak oxygen uptake: Twenty-seven of the 28 condition 1 participants (96%) and 20 of the 23 condition 2 participants (87%) returned for treadmill testing at the end of the 6-month maintenance period (Figure 1). Values of VO_2 max at 12 months were 4% and 5% lower than at 6 months in subjects of condition 1 and 2, respectively (both $p < 0.05$) (Figure 3). The values of VO_2 max at 12 months exceeded those at

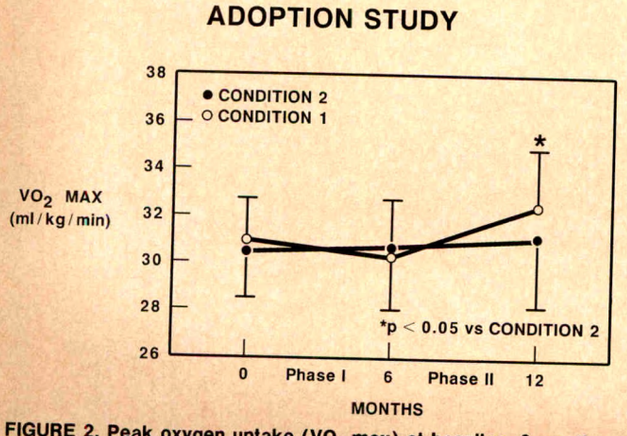

FIGURE 2. Peak oxygen uptake (VO_2 max) at baseline, 6 months and 12 months by adoption condition.

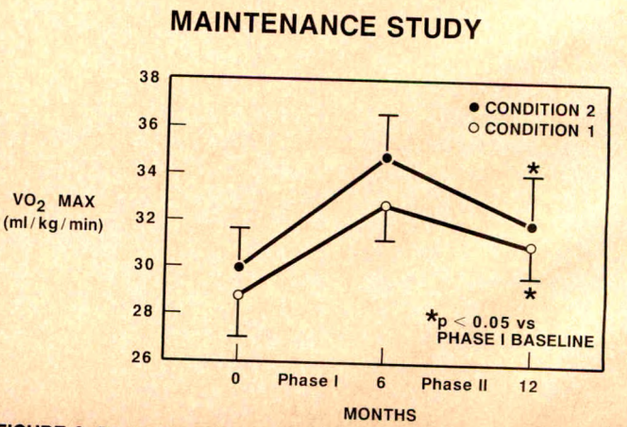

FIGURE 3. Peak oxygen uptake (VO_2 max) at baseline, 6 months and 12 months by maintenance condition.

baseline by 8% ($p < 0.001$) and 7% ($p < 0.04$) in condition 1 and 2 subjects, respectively. Values of VO_2 max throughout phases I and II of the study are shown in Table III.

Correlations between self-reported adherence and changes in peak oxygen uptake: Change in VO_2 max was significantly correlated with the number of exercise sessions reported per month ($r = 0.31$, $p < 0.05$). Ratings of the enjoyment of sessions were positively related to the reported duration of sessions ($r = 0.50$, $p < 0.005$) and the perceived convenience of exercise sessions ($r = 0.60$, $p < 0.005$).

Discussion

This was 1 of the first studies to systematically evaluate factors influencing the adoption and maintenance of exercise over a 6-month period. The behavioral strategies for enhancing the adoption of exercise included goal-setting, self-monitoring, instruction in relapse prevention and supportive feedback provided by telephone contact with staff. Gains achieved during the first 6 months were maintained over the second 6 months by self-directed monitoring and relapse prevention.

In the adoption of exercise, the first 6 months are considered crucial.[13,14] The results of the present study reveal that a home-based, individually prescribed program of moderate-intensity exercise accompanied by regularly scheduled staff phone contacts is associated with a high degree of adherence and a significant increase in peak oxygen uptake in healthy middle-aged individuals. Participants in the adoption study received an average of 30 minutes of initial face-to-face instruction by staff and <60 minutes of subsequent phone contact with staff during the entire 6-month period. In contrast, group-supervised exercise training programs usually entail 72 hours of face-to-face contact over a similar period.[15]

The adoption of a new health behavior such as physical exercise requires the mastery of new skills. In addition to increasing their activity gradually, so as to avoid excessive fatigue and injury, individuals need to learn how to restructure their environment to support the new activity. This entails changing time schedules, adjusting to the sensations generated by aerobic activity, such as perspiration and increased heart rate and breathing, and altering attitudes that impede participation such as the belief among some women that perspiring is "unladylike" and hence undesirable.

Social support is often important in the early stages of adoption, when the benefits of exercise have yet to be experienced and activity-related discomfort is at its peak.[12] However, this need not require prolonged personal contact, for telephone contact is a convenient alternative.[8,9] In the adoption study, only the subjects who received supportive telephone contact from the staff significantly increased their oxygen uptake.

Strategies to maintain adopted exercise patterns differ from those used to promote the adoption of exercise habits.[16,17] In the current study, maintenance procedures were largely *self-directed* rather than *staff-directed*. Individuals monitored their own progress and implemented relapse prevention strategies when their exercise efforts began to slacken. This model of ongoing self-regulation has been utilized by Bandura and Simon to counteract relapse in obesity.[18]

Subjects in the maintenance study reported a high rate of adherence to exercise and exhibited a peak oxygen uptake at 12 months that exceeded that at the beginning of the Phase I study. However, adherence tips and guideline provided to subjects in condition 1 did not maintain their peak oxygen uptake at levels higher than those of subjects in condition 2. Both groups of subjects appear to have mastered relapse-prevention strategies during the 6-month adoption phase preceding the maintenance study.

In many group-based exercise programs the dropout rate at 6 months approaches 50%.[19] Apparently the inconvenience of attending a class may outweigh the advantages of information and support provided by the group. We found that convenience and enjoyment of exercise significantly influenced both the adoption and maintenance of exercise, which underscores the need to develop regimens that maximize these factors. One important feature of the present study was the provision of a slightly lower than customary intensity of exercise. The training heart rate range was 65 to 77% of the peak value, compared to the 70% to 85% usually prescribed. This lower intensity, by 10 beats per minute, contributed to the comfort of exercise, especially among middle-aged individuals.[8,9]

The minimal staff effort and the convenience of home-based programs relying on staff telephone contact facilitate participation in monitored exercise at a relatively low cost. For example, individuals who have undergone baseline medical evaluation including exercise testing could receive 6 months of home-based exercise training using staff-initiated telephone contacts for approximately $30. This includes 30 minutes of initial instruction and 60 minutes of telephone feedback provided by staff at $20 per hour. This approach obviates the need for a group facility such as a gymnasium and thus greatly expands the availability of exercise training for healthy middle-aged individuals.

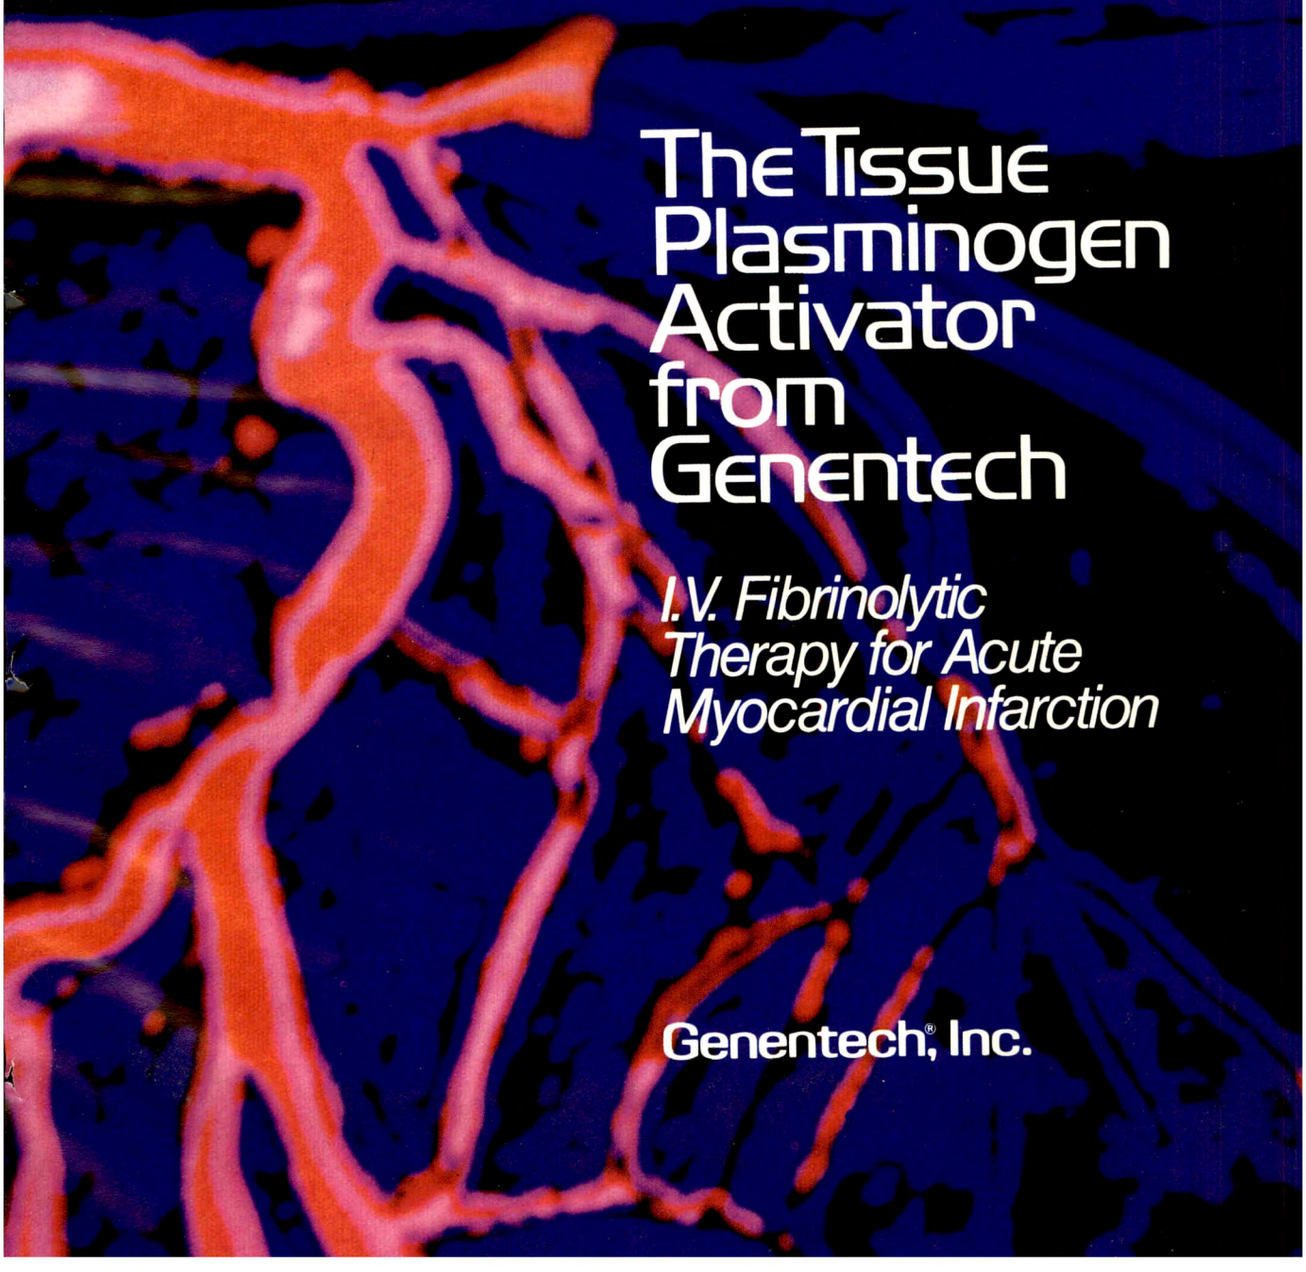
Introducing NEW

rt-PA™ ACTIVASE®

Alteplase, recombinant



The Tissue Plasminogen Activator from Genentech

I.V. Fibrinolytic Therapy for Acute Myocardial Infarction

Genentech®, Inc.

NEW

ACTIVASE®

Alteplase, recombinant

A tissue plasminogen activator

The biopharmaceutical equivalent of the body's own natural

t-PA

IN ACUTE MYOCARDIAL INFARCTION,

TIME IS MUSCLE

...Rapid dissolution of occlusive coronary thrombi

...High rate of recanalization

...Preservation of ventricular function

...Excellent safety profile

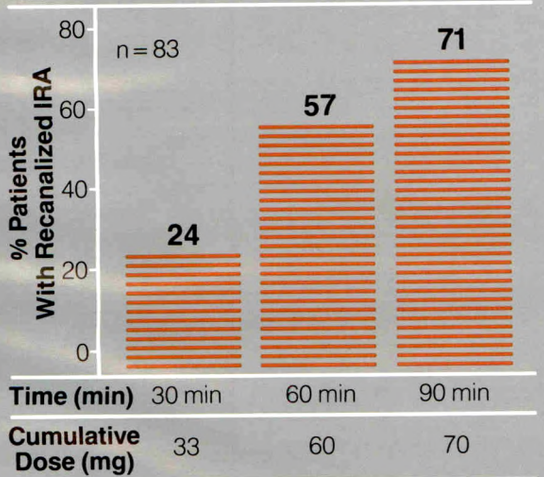
FIBRINOLYTIC EFFICACY

ACTIVASE® OPENS CORONARY ARTERIES

Fast

▲ The Average Time to Successful Recanalization is Between 30 and 60 Minutes.[1]

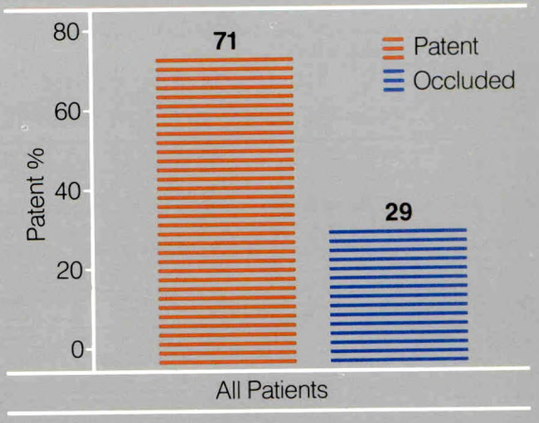
RECANALIZATION RATE FOLLOWING ACTIVASE® THERAPY 100 MG/3 HRS



Effectively

▲ 71% Recanalization Demonstrated in Acute MI Patients[1]

RECANALIZATION RATE 90 MINUTES AFTER ACTIVASE® THERAPY NIH-TIMI B TRIAL



...And Keeps Them Open

Low Reocclusion Rate:

▲ Pooled incidence of reocclusion was less than 13% after ACTIVASE® administration.[2]

Alteplase, recombinant

I.V. fibrinolytic therapy for acute myocardial infarction

NEW

ACTIVASE®
Alteplase, recombinant

MYOCARDIAL SALVAGE

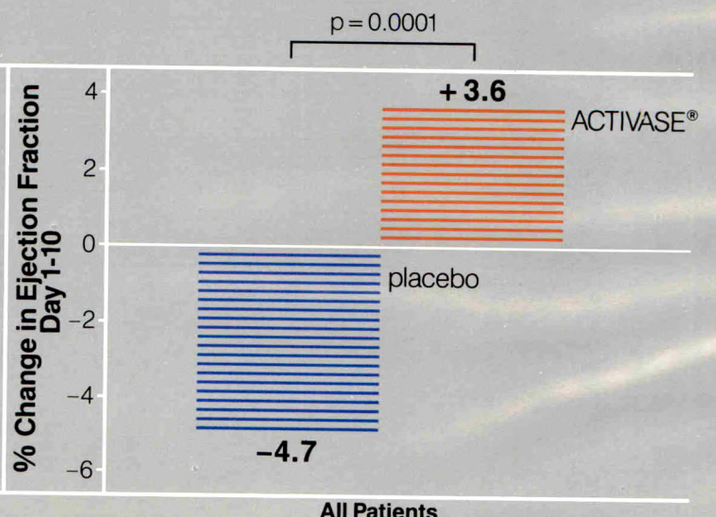
ACTIVASE® IMPROVES LEFT VENTRICULAR FUNCTION

▲ Significant Difference in Ejection Fraction Between Placebo and ACTIVASE®-Treated Patients[3]

Well-controlled studies document significant preservation of ventricular function:

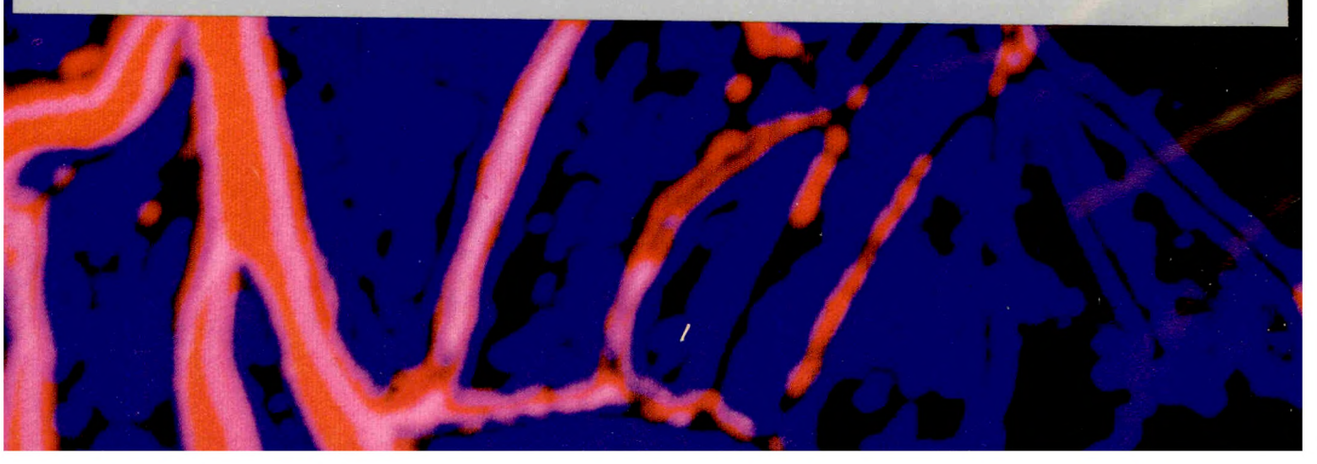
1. *The JOHNS HOPKINS Study*

At day 10 after acute myocardial infarction, patients treated with ACTIVASE® had a statistically significant recovery of ejection fraction, while placebo patients had a further deterioration from baseline.



▲ In Addition, There Was a 58% Reduction in the Incidence of Congestive Heart Failure Following MI in the ACTIVASE®-Treated Group. (p = 0.009)[3]

3. Guerci AD, Gerstenblith G, Brinker JA, et al: A randomized trial of intravenous tissue plasminogen activator for acute myocardial infarction with subsequent randomization to elective coronary angioplasty. *N Engl J Med* 1987; 317:1613-1618.



In Acute Myocardial Infarction,

TIME IS MUSCLE

2. The TICO Trial[4] *(THROMBOLYSIS IN CORONARY OCCLUSION)*

Following acute MI, and administration of ACTIVASE® or placebo, contrast ventriculogram and radionuclide gated scans were performed.

Results showed that ACTIVASE®-treated patients had significantly greater residual left ventricular ejection fractions at discharge.

Alteplase, recombinant

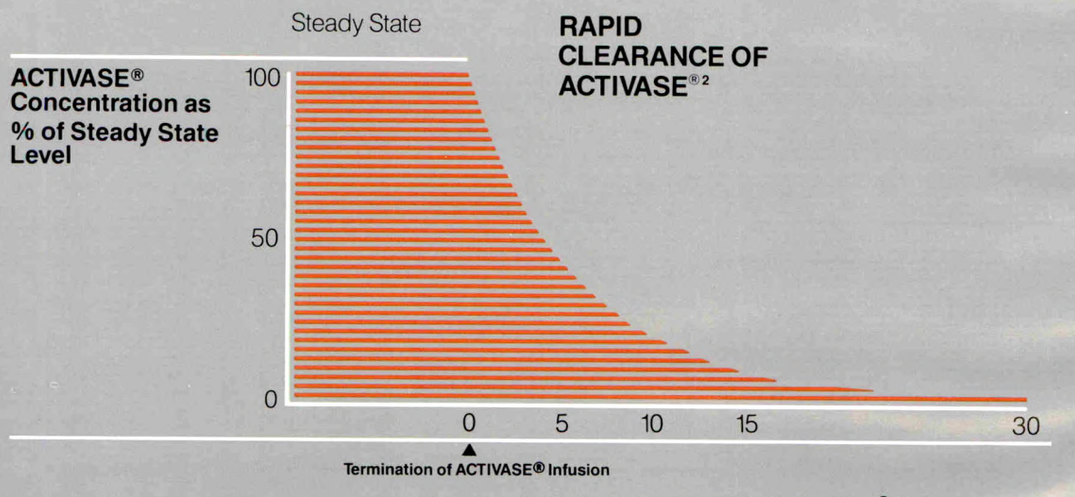
FIBRINOLYTIC SAFETY

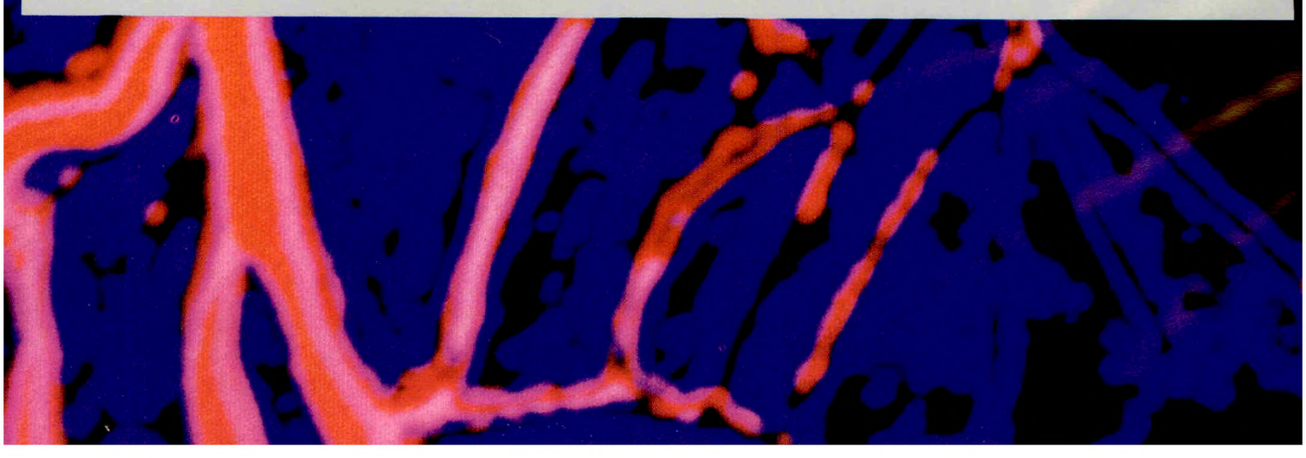
EXCELLENT SAFETY PROFILE IN ACUTE MI:

▲ FIVE-MINUTE HALF-LIFE AND FIBRIN SPECIFICITY Lower the Risk of Serious Bleeding in Emergency Procedures Such as Hemodynamic Monitoring, Angioplasty and Bypass Surgery (CABG).



▲ ACTIVASE® Is Identical to Human Tissue Plasminogen Activator (t-PA). No Serious or Life-Threatening Reactions Have Been Reported.

2. Data on file, Genentech, Inc.



In Acute Myocardial Infarction,

TIME IS MUSCLE

Bleeding is the Most Common Complication of Thrombolytic Therapy

INCIDENCE OF BLEEDING COMPLICATIONS FOLLOWING ACTIVASE® IN 848 PATIENTS:

Bleeding site	Clinically significant events %
–Arterial catheterization site	20
–Gastrointestinal (GI)	5
–Venipuncture	4
–Hematuria	4
–Occult GI	1
–Microscopic hematuria	1
–Ecchymosis	1
–Retroperitoneal	< 1
–Intracranial	0.4

Careful Patient Selection Can Optimize the Benefit-to-Risk Ratio. Consider These Factors in Evaluating an Individual for ACTIVASE® Therapy:

CONTRAINDICATIONS

–Active internal bleeding
–History of cerebrovascular accident
–Recent (within two months) intracranial or intraspinal surgery or trauma (see WARNINGS)
–Intracranial neoplasm, arteriovenous malformation, or aneurysm
–Known bleeding diathesis
–Severe uncontrolled hypertension

Please see ACTIVASE® (Alteplase) full prescribing information at end of this advertisement.

ACTIVASE®
Alteplase, recombinant

I.V. fibrinolytic therapy for acute myocardial infarction

NEW

ACTIVASE®
Alteplase, recombinant

In Acute Myocardial Infarction,
TIME IS MUSCLE

Rationale for ACTIVASE® Therapy

Acute MI is an evolving process caused by an occlusive coronary thrombus

I.V. administration of ACTIVASE®:

- *Opens coronary arteries rapidly, effectively, and keeps them open*
- *Improves left ventricular function, and reduces incidence of congestive heart failure*
- *Prompt intervention possible shortly after ACTIVASE® therapy due to excellent safety profile—compatible with angioplasty, bypass surgery and hemodynamic monitoring*

ACTIVASE® is a potent agent, and the benefit-to-risk ratio should be carefully considered in every patient

ACTIVASE® Dosage Schedule

Lytic dose	Bolus Hr 1	6-10mg 50-54mg
Maintenance Dose	Hr 2 Hr 3	20mg 20mg
TOTAL Recommended Dose		100mg

ACTIVASE®
Alteplase, recombinant
I.V. fibrinolytic therapy for acute myocardial infarction

ACTIVASE®
Alteplase, recombinant

DESCRIPTION: ACTIVASE®, Alteplase, is a tissue plasminogen activator produced by recombinant DNA technology. It is a sterile, purified glycoprotein of 527 amino acids. It is synthesized using the complementary DNA (cDNA) for natural human tissue-type plasminogen activator obtained from a human melanoma cell line. The manufacturing process involves the secretion of the enzyme, alteplase, into the culture medium by an established mammalian cell line (Chinese Hamster Ovary cells) into which the cDNA for alteplase has been genetically inserted.

ACTIVASE®, a sterile, white to off-white, lyophilized powder, is intended for intravenous administration after reconstitution with Sterile Water for Injection, USP. The quantitative composition of the lyophilized product is:

50 mg (29 million IU) Vial	20 mg (11.6 million IU) Vial
Alteplase 50 mg (29 million IU)	Alteplase 20 mg (11.6 million IU)
L-Arginine 1.7 g	L-Arginine 0.7 g
Phosphoric Acid 0.5 g	Phosphoric Acid 0.2 g
Polysorbate 80, less than 4 mg	Polysorbate 80, less than 1.6 mg

Phosphoric acid and/or sodium hydroxide may be used prior to lyophilization for pH adjustment.

Biological potency is determined by an *in vitro* clot lysis assay and is expressed in International Units as tested against the WHO standard. The specific activity of ACTIVASE® is 580,000 IU/mg.

CLINICAL PHARMACOLOGY: ACTIVASE® is an enzyme (serine protease) which has the property of fibrin-enhanced conversion of plasminogen to plasmin. It produces limited conversion of plasminogen in the absence of fibrin. When introduced into the systemic circulation at pharmacologic concentration, ACTIVASE® binds to fibrin in a thrombus and converts the entrapped plasminogen to plasmin. This initiates local fibrinolysis with limited systemic proteolysis. Following administration of 100 mg ACTIVASE®, there is a decrease (16-36%) in circulating fibrinogen.[1,2,3] In a controlled trial, 8 of 73 patients (11%) receiving ACTIVASE® (1.25 mg/kg body weight over 3 hours) experienced a decrease in fibrinogen to below 100 mg/dL.[2]

ACTIVASE® is cleared rapidly from circulating plasma at a rate of 550-680 mL/min. ACTIVASE® is cleared primarily by the liver. More than 50% of ACTIVASE® present in plasma is cleared within 5 minutes after the infusion has been terminated, and approximately 80% is cleared within 10 minutes.

Coronary occlusion due to a thrombus is present in the infarct-related coronary artery in approximately 80% of patients experiencing a transmural myocardial infarction evaluated within four hours of onset of symptoms.[4,5]

In patients studied in a controlled trial with coronary angiography at 90 and 120 minutes following infusion of ACTIVASE®, infarct artery patency was observed in 71% and 85% of patients (n=85), respectively.[2,3] In a second study, where patients received coronary angiography prior to and following infusion of ACTIVASE® within six hours of the onset of symptoms, reperfusion of the obstructed vessel occurred within 90 minutes after the commencement of therapy in 71% of 83 patients.[1]

In a double blind, randomized trial (138 patients) comparing ACTIVASE® to placebo, patients infused with ACTIVASE® within 4 hours of onset of symptoms experienced improved left ventricular function at day 10 compared to the placebo group, when ejection fraction was measured by gated blood pool scan (53.2% versus 46.4%, p=0.018). Relative to baseline (day 1) values, the net changes in ejection fraction were +3.6% and -4.7% for the treated and placebo group, respectively (p=0.0001). Also documented was a reduced incidence of clinical congestive heart failure in the treated group (14%) compared to the placebo group (33%) (p=0.009).[3]

In a second double blind, randomized trial (136 patients) comparing ACTIVASE®, Alteplase, to placebo, patients infused with ACTIVASE® within 2.5 hours of onset of symptoms experienced improved left ventricular function at a mean of 21 days compared to the placebo group, when ejection fraction was measured by gated blood pool scan (54% versus 48%, p=0.008) and by contrast ventriculogram (62% versus 54%, p=0.002). Although the contribution of ACTIVASE® alone is unclear, the incidence of nonischemic cardiac complications when taken as a group (i.e., congestive heart failure, pericarditis, atrial fibrillation, conduction disturbance) was reduced compared to those patients treated with placebo (p<0.01).[3]

INDICATIONS AND USAGE: ACTIVASE® is indicated for use in the management of acute myocardial infarction (AMI) in adults for the lysis of thrombi obstructing coronary arteries, the improvement of ventricular function and reduction of the incidence of congestive heart failure. Treatment should be initiated as soon as possible after the onset of AMI symptoms (see CLINICAL PHARMACOLOGY).

CONTRAINDICATIONS: Because thrombolytic therapy increases the risk of bleeding, ACTIVASE® is contraindicated in the following situations: • Active internal bleeding • History of cerebrovascular accident • Recent (within two months) intracranial or intraspinal surgery or trauma (see WARNINGS) • Intracranial neoplasm, arteriovenous malformation, or aneurysm • Known bleeding diathesis • Severe uncontrolled hypertension.

WARNINGS: Bleeding The most common complication encountered during ACTIVASE® therapy is bleeding. The type of bleeding associated with thrombolytic therapy can be divided into two broad categories: • Internal bleeding involving the gastrointestinal tract, genitourinary tract, retroperitoneal or intracranial sites • Superficial or surface bleeding, observed mainly at invaded or disturbed sites (e.g., venous cutdowns, arterial punctures, sites of recent surgical intervention).

The concomitant use of heparin anticoagulation may contribute to the bleeding. Some of the hemorrhagic episodes occurred one or more days after the effects of ACTIVASE® had dissipated, but while heparin therapy was continuing.

As fibrin is lysed during ACTIVASE® therapy, bleeding from recent puncture sites may occur. Therefore, thrombolytic therapy requires careful attention to all potential bleeding sites (including catheter insertion sites, arterial and venous puncture sites, cutdown sites and needle puncture sites).

Intramuscular injections and nonessential handling of the patient should be avoided during treatment with ACTIVASE®. Venipunctures should be performed carefully and only as required.

Should an arterial puncture be necessary during an infusion of ACTIVASE®, it is preferable to use an upper extremity vessel that is accessible to manual compression. Pressure should be applied for at least 30 minutes, a pressure dressing applied and the puncture site checked frequently for evidence of bleeding.

Should serious bleeding (not controllable by local pressure) occur, the infusion of ACTIVASE®, Alteplase, and any concomitant heparin should be terminated immediately.

Each patient being considered for therapy with ACTIVASE® should be carefully evaluated and anticipated benefits weighed against potential risks associated with therapy.

In the following conditions, the risks of ACTIVASE® therapy may be increased and should be weighed against the anticipated benefits: • Recent (within 10 days) major surgery, e.g., coronary artery bypass graft, obstetrical delivery, organ biopsy, previous puncture of noncompressible vessels • Cerebrovascular disease • Recent gastrointestinal or genitourinary bleeding (within 10 days) • Recent trauma (within 10 days) • Hypertension: systolic BP ≥ 180 mm Hg and/or diastolic BP ≥ 110 mm Hg • High likelihood of left heart thrombus, e.g., mitral stenosis with atrial fibrillation • Acute pericarditis • Subacute bacterial endocarditis • Hemostatic defects including those secondary to severe hepatic or renal disease • Significant liver dysfunction • Pregnancy • Diabetic hemorrhagic retinopathy, or other hemorrhagic ophthalmic conditions • Septic thrombophlebitis or occluded AV cannula at seriously infected site • Advanced age, i.e., over 75 years old • Patients currently receiving oral anticoagulants, e.g., warfarin sodium • Any other condition in which bleeding constitutes a significant hazard or would be particularly difficult to manage because of its location.

Arrhythmias Coronary thrombolysis may result in arrhythmias associated with reperfusion. These arrhythmias (such as sinus bradycardia, accelerated idioventricular rhythm, ventricular premature depolarizations, ventricular tachycardia) are not different from those often seen in the ordinary course of acute myocardial infarction and may be managed with standard antiarrhythmic measures. It is recommended that antiarrhythmic therapy for bradycardia and/or ventricular irritability be available when infusions of ACTIVASE® are administered.

PRECAUTIONS: General Standard management of myocardial infarction should be implemented concomitantly with ACTIVASE® treatment. Noncompressible arterial puncture must be avoided (i.e., internal jugular and subclavian punctures should be avoided to minimize bleeding from noncompressible sites). Arterial and venous punctures should be minimized. In the event of serious bleeding, ACTIVASE® and heparin should be discontinued immediately. Heparin effects can be reversed by protamine.

Readministration There is no experience with readministration of ACTIVASE®. If an anaphylactoid reaction occurs, the infusion should be discontinued immediately and appropriate therapy initiated.

Although sustained antibody formation in patients receiving one dose of ACTIVASE® has not been documented, readministration should be undertaken with caution. Detectable levels of antibody (a single point measurement) were reported in one patient but subsequent antibody test results were negative.

Laboratory Tests During ACTIVASE® therapy, if coagulation tests and/or measures of fibrinolytic activity are performed, the results may be unreliable unless specific precautions are taken to prevent *in vitro* artifacts. ACTIVASE® is an enzyme that when present in blood in pharmacologic concentrations remains active under *in vitro* conditions. This can lead to degradation of fibrinogen in blood samples removed for analysis. Collection of blood samples in the presence of aprotinin (150-200 units/mL) can to some extent mitigate this phenomenon.

Drug Interactions The interaction of ACTIVASE® with other cardioactive drugs has not been studied. In

addition to bleeding associated with heparin and vitamin K antagonists, drugs that alter platelet function (such as acetylsalicylic acid, dipyridamole) may increase the risk of bleeding if administered prior to, during or after ACTIVASE® Alteplase, therapy.

Use of Anticoagulants Heparin has been administered concomitantly with and following infusions of ACTIVASE® to reduce the risk of rethrombosis. Because either heparin or ACTIVASE® alone may cause bleeding complications, careful monitoring for bleeding is advised, especially at arterial puncture sites.

Pregnancy (Category C) Animal reproduction studies have not been conducted with ACTIVASE®. It is also not known whether ACTIVASE® can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. ACTIVASE® should be given to a pregnant woman only if clearly needed.

Pediatric Use Safety and effectiveness of ACTIVASE® in children has not been established.

Carcinogenesis, Mutagenesis, Impairment of Fertility Long-term studies in animals have not been performed to evaluate the carcinogenic potential or the effect on fertility. Short-term studies, which evaluated tumorigenicity of ACTIVASE® and effect on tumor metastases in rodents, were negative.

Studies to determine mutagenicity (Ames test) and chromosomal aberration assays in human lymphocytes were negative at all concentrations tested. Cytotoxicity, as reflected by a decrease in mitotic index, was evidenced only after prolonged exposure and only at the highest concentrations tested.

Nursing Mothers It is not known whether ACTIVASE® is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when ACTIVASE® is administered to a nursing woman.

ADVERSE REACTIONS: Bleeding The most frequent adverse reaction associated with ACTIVASE® is bleeding. The type of bleeding associated with thrombolytic therapy can be divided into two broad categories: • Internal bleeding, involving the gastrointestinal tract, genitourinary tract, retroperitoneal or intracranial sites • Superficial or surface bleeding, observed mainly at invaded or disturbed sites (e.g., venous cutdowns, arterial punctures, sites of recent surgical intervention).

The following incidence of significant internal bleeding (estimated as > 250 cc blood loss) has been reported in studies in over 800 patients treated at all doses:

	Total Dose ≤ 100 mg	Total Dose > 100 mg
gastrointestinal	5%	5%
genitourinary	4%	4%
ecchymosis	1%	< 1%
retroperitoneal	< 1%	< 1%
epistaxis	< 1%	< 1%
gingival	< 1%	< 1%

The incidence of intracranial bleeding (ICB) in patients treated with ACTIVASE® is as follows:

Dose	Number of Patients	%
100 mg	3272	0.4
150 mg	1779	1.3
1-1.4 mg/kg	237	0.4

These data indicate that a dose of 150 mg of ACTIVASE® should not be used because it has been associated with an increase in intracranial bleeding.

Although fatalities due to intracranial bleeding have been observed during and after ACTIVASE® therapy, an analysis of data from three controlled clinical trials in acute myocardial infarction revealed no evidence of increased overall in-hospital mortality. While not statistically significant, in-hospital mortality in patients treated with ACTIVASE® Alteplase, was lower (4.7%, 11/232) compared to patients not receiving ACTIVASE® (6.8%, 11/162).[3]

Should serious bleeding in a critical location (intracranial, gastrointestinal, retroperitoneal, pericardial) occur, ACTIVASE® therapy should be discontinued immediately, along with any concomitant therapy with heparin.

Fibrin which is part of the hemostatic plug formed at needle puncture sites will be lysed during ACTIVASE® therapy. Therefore, ACTIVASE® therapy requires careful attention to potential bleeding sites, e.g., catheter insertion sites, arterial puncture sites.

Allergic Reactions No serious or life-threatening allergic reactions have been reported. Other mild hypersensitivity reactions such as urticaria have been observed occasionally.

Other Adverse Reactions Other adverse reactions have been reported, principally nausea and/or vomiting, hypotension, and fever. These reactions are frequent sequelae of myocardial infarction and may or may not be attributable to ACTIVASE® therapy.

DOSAGE AND ADMINISTRATION: Administer ACTIVASE® as soon as possible after the onset of symptoms.

Lysis of coronary artery thrombi has been documented in 71% of patients treated with ACTIVASE® within 6 hours of onset of symptoms.[1] Improvement of ventricular function and reduction of the incidence of congestive heart failure have been documented in patients treated within 4 hours of the onset of symptoms.[3]

ACTIVASE® is intended for administration by intravenous infusion only.

The recommended dose is 100 mg administered as 60 mg (34.8 million IU) in the first hour (of which 6 to 10 mg is administered as a bolus over the first 1-2 minutes), 20 mg (11.6 million IU) over the second hour, and 20 mg (11.6 million IU) over the third hour. For smaller patients (less than 65 kg), a dose of 1.25 mg/kg administered over 3 hours, as described above, may be used.[5]

A DOSE OF 150 MG OF ACTIVASE, ALTEPLASE, SHOULD NOT BE USED BECAUSE IT HAS BEEN ASSOCIATED WITH AN INCREASE IN INTRACRANIAL BLEEDING.

Although the use of anticoagulants and antiplatelet drugs during and following administration of ACTIVASE® has not been shown to be of unequivocal benefit, heparin has been administered concomitantly for 48 hours or longer in more than 90% of patients. Aspirin and/or dipyridamole have been given either during and/or following heparin treatment.

Reconstitution and Dilution DO NOT USE IF VACUUM IS NOT PRESENT.

ACTIVASE® should be reconstituted by aseptically adding the appropriate volume of the accompanying Sterile Water for Injection, USP to the vial. It is important that ACTIVASE® be reconstituted only with Sterile Water for Injection, USP, without preservatives. Do not use Bacteriostatic Water for Injection, USP. The reconstituted preparation results in a colorless to pale yellow transparent solution containing ACTIVASE® 1.0 mg/mL at approximately pH 7.3. The osmolality of this solution is approximately 215 mOsm/kg.

Reconstitution should be carried out using a large bore needle (e.g., 18 gauge), directing the stream of Sterile Water for Injection, USP into the lyophilized cake. Slight foaming upon reconstitution is not unusual; standing undisturbed for several minutes is usually sufficient to allow dissipation of any large bubbles.

Because ACTIVASE® contains no antibacterial preservatives, it should be reconstituted immediately before use. The solution may be used for direct intravenous administration within 8 hours following reconstitution when stored between 2-30°C. Before further dilution or administration the product should be visually inspected for particulate matter and discoloration prior to administration whenever solution and container permit.

ACTIVASE® Alteplase, may be administered as reconstituted at 1.0 mg/mL. As an alternative, the reconstituted solution may be diluted further immediately before administration in an equal volume of 0.9% Sodium Chloride Injection, USP or 5% Dextrose Injection, USP to yield a concentration of 0.5 mg/mL. Either polyvinyl chloride bags or glass bottles are acceptable. ACTIVASE® is stable for up to 8 hours in these solutions at room temperature. Exposure to light has no effect on the stability of these solutions. Excessive agitation during dilution should be avoided; mixing should be accomplished with gentle swirling and/or slow inversion. Do not use other infusion solutions, e.g., Sterile Water for Injection, USP or preservative-containing solutions for further dilution.

No other medication should be added to infusion solutions containing ACTIVASE®. Any unused infusion solution should be discarded.

HOW SUPPLIED: ACTIVASE® is supplied as a sterile, lyophilized powder in 20 mg and 50 mg vials containing vacuum.

Each 20 mg ACTIVASE® vial (11.6 million IU) is packaged with diluent for reconstitution. (20 mL Sterile Water for Injection, USP): NDC 50242-044-12.

Each 50 mg ACTIVASE® vial (29.0 million IU) is packaged with diluent for reconstitution. (50 mL Sterile Water for Injection, USP): NDC 50242-044-13.

Storage Store lyophilized ACTIVASE® at controlled room temperature not to exceed 30°C (86°F), or under refrigeration (2-8°C/36-46°F). Protect the lyophilized material during extended storage from excessive exposure to light.

Do not use beyond the expiration date stamped on the vial.

Optimum Heart Rate of Large Failing Hearts

HERBERT J. LEVINE, MD

". . . like warp and woof, mechanism and teleology are interwoven together, and we must not cleave to one nor despise the other for their union is rooted in the very nature of totality."

Sir D'Arcy Wentworth Thompson

Big hearts beat more slowly than small hearts. While this observation seems patent and even borders on tautology, the reasons for it may not be quite so obvious. The inherent frequency of a large machine will be slower than that of a similar small machine. It boggles the mind to imagine an elephant heart with atrial fibrillation beating at a rate of 180 beats/min, yet it does not surprise us that a human heart weighing 300 g might do so. Little consideration has been given in clinical medicine to adjusting heart rate (HR) to heart size. What is the intrinsic frequency of an 800-g heart in a patient with systemic hypertension, hypertrophic cardiomyopathy or idiopathic dilated cardiomyopathy? Should the optimal HR for pacemaker-dependent patients be normalized for heart size? Should we not expect a slower HR in patients with aortic stenosis or systemic hypertension than in those with mild mitral valve disease?

To answer these questions, one might begin with an allometric analysis of relevant biologic parameters among animals of different size. Examining the relation between resting HR and body mass among mammals spanning a body weight from 3,000 kg (elephant) to 3 g (shrew), a linear relation between logarithmic coordinates is observed.[1] Furthermore, because heart weight is nearly proportional to body weight (comprising 0.6% of body weight in small and large mammals alike), an inverse relation between heart weight and HR can be established. In addition, the regression line on logarithmic coordinates between body mass and resting oxygen consumption among mammals has exactly the same slope as that between body mass and HR.[1] Thus, from these data it may be concluded that the HR increase in smaller mammals is in exact proportion to the increase in metabolic rate. Such increases are the consequence of a biophysical imperative. Since heat production will depend on the mass (the cube of a linear dimension) and heat loss through the surface of an organism as the square of a linear dimension, as an animal becomes smaller, the ratio of surface area to mass increases and the relative heat loss will increase, necessitating a rise in metabolic rate to provide the same quantity of usable energy. Thus, while human beings consume 1 to 2% of their body weight in food per day, a mouse will devour 50% of its body weight daily.

On the basis of these observations, it is reasonable to conclude that the slower HRs in larger mammals are the consequence of a lower metabolic rate. However, if the inverse relation between intrinsic HR and heart size is valid for humans with varying degrees of cardiomegaly, a different explanation must be sought, since a number of studies have shown that resting unit myocardial oxygen consumption in patients with large failing hearts is normal despite heart weights which may be as much as 3 times heavier than normal.[2,3] Thus, a slower HR in large human hearts cannot be attributed to a lower myocardial metabolic rate. There is reason to believe that other factors may determine the intrinsic frequency of hearts of varying size. Birds have bigger hearts and slower HRs than mammals of equal size. In addition, their cardiac output is higher for a given metabolic rate and the allometric relation between oxygen consumption and body mass predicts that a 1-kg bird will have a higher oxygen consumption than a 1-kg mammal.[4] According to Grubb,[4] the HR of a 1-kg bird will be 178 beats/min whereas that of a comparable sized mammal will be 236 beats/min. It would appear, therefore, that the slower HR in birds compared with mammals is not related to metabolic rate and may be a consequence of the larger heart size itself.

Support for this possibility may be found in Froude's law of the correspondence of speeds. This law states that speed varies as the square root of the linear dimension. As illustrated by Sir D'Arcy Thompson, this principle has provided an accurate basis for comparing the maximum speed of fish, ships or birds in flight and in relating a variety of other biologic phe-

nomena.[5] More relevant to the question of the HR of hearts of differing size, is the application of Froude's law which dictates that, among similar pendulums, the time of the swing varies as the square root of the pendulum length.[5] If we were to apply this principle to the comparison of the intrinsic HR of a normal and enlarged heart (volume 3 times larger than normal) and assume the heart rate of the normal heart to be 75 beats/min, the linear dimension of the larger heart would be 1.44 times bigger than normal and the intrinsic heart rate 62 beats/min.

Hill, however, suggested that among animals the relation between speed and length is linear[6] and that allometric velocity characteristics are determined more by differences in metabolic rate than by Froude's law. In bird flight, wing-beat frequency is approximately inversely proportional to the linear dimension of the bird.[5] If such is the case, the intrinsic HR of the large heart described above would be 52 instead of 62 beats/min. Whether this approach is appropriate for humans is unknown and, unfortunately, allometric data of this sort derived from human studies is sparse. Harrison et al[7] examined the relation between myocardial fiber thickness and heart rate among normal human hearts from infancy to adulthood and provided some helpful information. As shown in Figure 1, the relation between myocardial fiber thickness and HR among normal infants, children and adults appears to be exponential. However, the HRs of large, nonfailing and failing hearts were considerably faster than those we would have predicted from the semi-logarithmic relation derived from normal hearts. Thus, the HRs of these large nonfailing and failing hearts were observed to be 84 and 76 beats/min, whereas extrapolation of the data obtained from the normal hearts would predict these values to be 33 and 8 beats/min, respectively. Because the data from normal hearts were derived from humans with marked variations in body

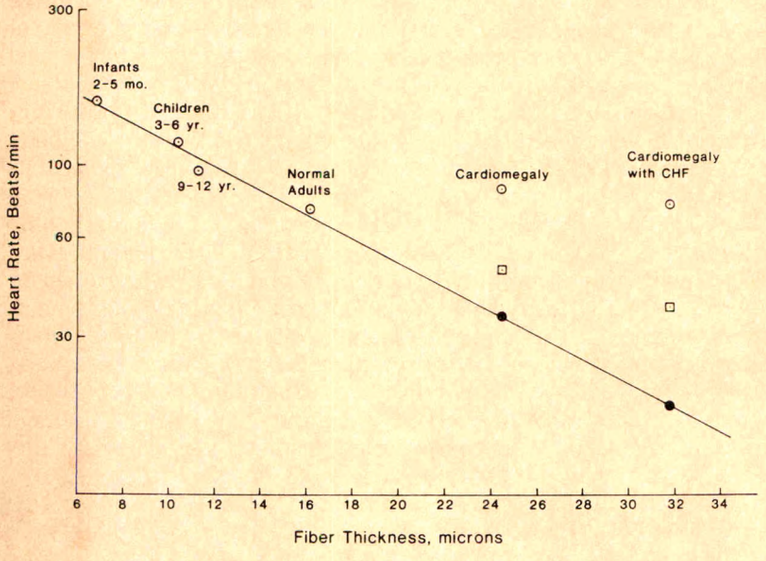

FIGURE 1. Relation between heart rate and myocardial fiber thickness. Values for normal infants, children and adults, and adult patients with large, nonfailing and failing hearts are indicated by the *open circles* (data from Harrison et al).[7] The *solid circles* indicate the heart rate predicted for patients with cardiomegaly (with and without congestive heart failure), extrapolated from the data obtained from normal hearts. The *open squares* indicate the heart rate calculated by assuming an inverse linear relation between fiber thickness and heart rate (see text). CHF = congestive heart failure.

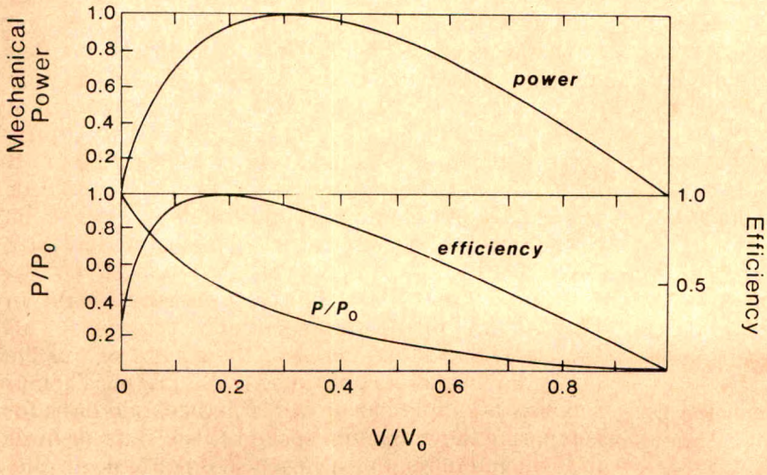

FIGURE 2. Relation between various mechanical properties of muscle and speed of shortening. Speed (V) as fraction of maximum speed (V_0) under zero load. Force (P) as fraction of maximum force (P_0) at zero speed. Efficiency equals mechanical work done divided by total energy used. Mechanical power equals the product of force and speed (PV). From experiments on isolated muscles and on man. Adapted from Hill.[6]

size, the metabolic rate was not constant and thus the allometric analysis of HR rate must be adjusted accordingly. The real question to be solved is the reaction between HR and heart size when the myocardial metabolic rate remains constant. Assuming, as Hill suggests, that the inverse relation between frequency and linear dimension of heart muscle (fiber thickness) is linear rather than exponential, the predicted HR in these 2 groups of large hearts would be 48 and 37 beats/min (Figure 1).

Whether these allometric comparisons should employ linear or exponential functions is problematical. What is clear, is that given their druthers, large hearts would rather beat more slowly than normal sized hearts. The impact of this conclusion becomes greater when we consider that a general response of the failing heart is an increase in HR. Whereas this might not be of concern during the acute phase of heart failure, as cardiac dilatation and hypertrophy evolve, the increase in HR may not be entirely self-serving. The HR response is an effective mechanism for compensating for reduced contractile performance and reduced stroke volume. Indeed, the enhanced neurohumoral activity of the sympathetic nervous system in congestive heart failure provides the mechanism for this adaptation. Yet, although there are HR-increasing forces at play in hypertrophy and failure, other changes may move velocity indexes in the opposite direction. In some species during pressure-overload hypertrophy and with aging, the myosin isoenzyme composition shifts to the predominant V_3 form with its characteristic reduced ATPase activity.[8] Among mammals of differing size, Barany[9] has shown a close correlation between myosin ATPase activity and the inherent speed of muscle shortening. Reduced myosin ATPase activity is also evident in the sluggish hearts of humans with congestive heart failure.[10]

For hearts of any size there appears to be an optimum frequency at which the power and efficiency of contraction are near maximum. Although the specific relation between these variables may not be known, analogous data regarding the mechanical properties of muscle and the speed of shortening should provide a comparable model. In Figure 2, adapted from Hill,[6] the relation between load and velocity of shortening and the mechanical power and efficiency of muscle is shown. Maximal power and efficiency are achieved at approximately 0.2 to 0.3 times the maximal velocity, and at velocities above and below this level, power and efficiency fall off sharply. Whether the malefic effect of tachycardia in large hearts is due more to prolonged diffusion through thicker myocardial fibers, as suggested by Harrison et al,[7] or to inherent mechanical characteristics of large muscles is unknown. Regardless, it is clear that mismatch between HR and cardiac performance may have the same implications as does afterload mismatch in failing myopathic ventricles. The modern approach in treating congestive heart failure exploits afterload mismatch by interrupting compensatory systemic vascular constriction. Indeed, the success of this intervention may be due in part to the steep portion of the efficiency-load curve at high values of P/P_0 shown in Figure 2. In this circumstance, a reduction in afterload (P/P_0) would be expected to evoke a substantial increase in total power and efficiency of cardiac contraction. While the shape of the curve relating the optimal HR to the performance of large failing hearts is not known, the principle appears sound and is worthy of investigation.

The reports from Göteborg in 1975 of a beneficial effect of β-adrenergic blockade in patients with dilated cardiomyopathy[11] surprised cardiologists and were initially greeted with skepticism. After a decade of cautious experimentation, most investigators today believe that there are many patients with dilated cardiomyopathy who have improved ventricular performance and clinical status with this form of therapy. Although many explanations have been suggested, cardiac slowing is a constant feature of this therapy and quite possibly may be the change responsible for the benefit observed. With the availability of new specific bradycardiac agents relatively devoid of negative inotropism, hypotension and membrane effects,[12] the opportunity is at hand to test this hypothesis in clinical trials.

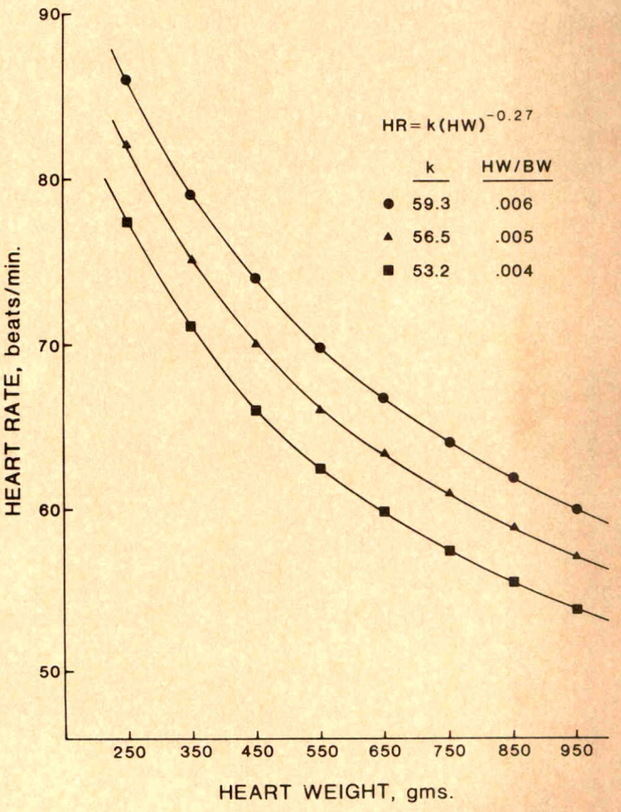

FIGURE 3. Relation between heart rate and heart weight. Adapted from Clark,[13] who suggests that heart rate varies in inverse proportion to the 0.27 power of body weight. The constants (k) assume the resting heart rate of a 70-kg man is 75 beats/min for heart weight/body weight ratios of 0.006 (●), 0.005 (▲) and 0.004 (■). BW = body weight; HR = heart rate; HW = heart weight; k = constant.

Perhaps the first step in examining the effects of heart size on the optimal HR would be to develop an algorithm applicable to clinical practice. Were it possible to accurately assess heart mass in cardiac patients, estimates of the inverse relation between HR and heart size could be derived by application of the principle of similitude in biology. Clark[13] has suggested that HR varies in inverse proportion to the 0.27 power of body weight. With this as a starting point, a rough approximation may be made of the variation in intrinsic HR expected to correspond to a range of heart size encountered in clinical medicine. The data presented in Figure 3 has been calculated by adapting the Clark formula to relate HR to heart weight. Using the constant derived from a heart weight/body weight ratio of 0.005, doubling a normal heart weight of 300 g would slow HR from 78 to 65 beats/min and a 3-fold increase in heart weight would predict an optimal HR of 58 beats/min. The patients with dilated cardiomyopathy reported by Waagstein et al[11] who benefited from β-adrenergic blockade had a mean fall in HR from 98 to 69 beats/min. These data provide only a crude estimate of the inverse relation between HR and heart size, but there is reason to believe that the expected values for the HR of large hearts are acceptable and in keeping with a number of biophysical predictions.

It would appear, that not only is there an optimal match between preload and the diastolic properties of the ventricle and between afterload and ventricular systolic function, but also between HR and the size and mechanical characteristics of the heart. Indeed, the interrelation between HR mismatch and both preload and afterload mismatch are obvious. In hypertrophic cardiomyopathy, prolongation of diastole alone will reduce elevated ventricular filling pressures and help compensate for delayed relaxation and reduced ventricular compliance. It is likely that the proper HR for optimal systolic function will not always be the same as that for optimal diastolic function, and the utility of bradycardiac therapy in patients with large hearts will need to be determined by trial. It is clear that the optimal HR must conform to nature's scale, and the warp and woof of this fabric is the relation of HR to cardiac mass.

Usefulness of Aspirin for Coronary Artery Disease

VALENTIN FUSTER, MD, MARC COHEN, MD, and JAMES H. CHESEBRO, MD

Aspirin was first synthesized in 1859. Because of its antipyretic and analgesic effects, relatively good tolerance, low cost and easy accessibility, aspirin continues to be the most consumed drug today. In the U.S. alone, between 20 and 30 billion tablets are ingested each year. Surprisingly, for such an old and often used drug, therapeutic discoveries are still being made. Further, aspirin's role in our number 1 public health problem, coronary artery disease, is still evolving.

In the late 1960s, aspirin, was discovered to have antiplatelet effects.[1] Its role in the prevention of coronary platelet thrombosis, then considered to be the cause of heart attacks, began to be anticipated. During the 1970s such hopes dissipated. First, the role of thrombosis in acute myocardial infarction was questioned. Second, a number of major drug trials of aspirin prophylaxis in survivors of myocardial infarction showed only a minor beneficial trend in the prevention of recurrent coronary events.

In the 1980s, a renewed interest in platelets and thrombosis, and consequently aspirin, has emerged especially in relation to acute coronary syndromes such as unstable angina and reocclusion after thrombolysis for acute myocardial infarction.[2-6] First, recent research has identified a definitive role for thrombosis in the pathogenesis of some acute coronary syndromes. Second, based on a better understanding of the natural history of coronary artery disease, drug trials of aspirin have been more properly designed allowing the benefits of the drug to become more apparent. Third, advances in the pharmacologic effects of aspirin are guiding investigators to search for the lowest dose of the drug with maximal anithrombotic effect and minimal risk of bleeding. Lastly, recent insights into platelet physiology indicate that aspirin alone may not be equally effective in all clinical settings involving platelet aggregation and thrombosis.

Role of Platelets and Thrombosis in the Acute Coronary Syndromes

Pathoanatomic studies: Pathoanatomic studies with meticulous histologic sectioning of the coronary arteries, including 100 to 1,000 sections of each segment with complicating thrombosis, have revealed that rupture, fissuring or ulceration of atherosclerotic plaques is a common autopsy finding in patients with coronary atherosclerotic disease experiencing fatal myocardial infarction or sudden death.[2-6] Over three-quarters of the ruptured atherosclerotic plaques have associated mural or occlusive thrombi.[2-6] Most important, most coronary artery thrombi have platelets at the base and are anchored in the cracks or ruptured atherosclertoic plaques.[2-7] Recent clinical investigations of acute coronary syndromes, applying different techniques, have confirmed this relation found at autopsy between plaque rupture and thrombosis; the techniques used were serial coronary arteriography,[8] retrieval of thrombi at operation during acute coronary artery syndromes,[9] reperfusion by thrombolysis,[10] angiographic morphology of ischemia-producing lesions both in vivo and using barium casts of the coronaries at postmortem[11,12] and intraoperative angioscopy.[7] Thus similar "anatomic accidents," consisting of plaque rupture and superimposed thrombosis, appear to be the most frequent cause of the acute coronary syndromes, including unstable angina, myocardial infarction and sudden coronary death.[13]

Physiologic studies: Physiologic studies have identified 5 important factors in the genesis of thrombi that complicate a ruptured atherosclerotic plaque.[13,14] They are (1) fibrillar collagen exposed to the flowing blood activates platelets and the intrinsic clotting cascade; (2) thromboplastin released from the damaged vessel activates the extrinsic clotting cascade forming thrombin, which leads not only to fibrin formation but also platelet aggregation; (3) hemorrhage into the plaque leads to release of adenosine diphosphate from erythocytes, which further amplifies platelet aggregation; (4) fatty gruel underneath the plaque is exposed to blood and activates platelets; and (5) luminal stenosis

by the plaque predisposes to turbulent blood flow, increased wall shear stress or stasis, all of which may promote platelet aggregation and thrombosis.

Clinical Trials of Aspirin

Secondary prevention trials: With the objective of preventing coronary thrombosis, 6 major controlled trials of aspirin prophylaxis in survivors of myocardial infarction were conducted in the 1970s. The trials showed a consistent trend toward a reduced incidence of recurrent myocardial infarction and death, but none achieved statistical significance.[15–20] Three main possibilities may explain the lack of a more striking beneficial effect. First, sample size may have been inadequate in view of the relatively low rate of reinfarction, a low *sensitivity* endpoint after transmural acute myocardial infarction. Second, the studies were done soon after myocardial infarction when early sudden death is known to be more closely related to irreversible ventricular dysfunction,[21] rather than to a preventable coronary thrombotic process that could potentially be prevented by aspirin. That is, a low *specificity* endpoint may also partly explain the lack of striking benefit in the aspirin-treated groups. In this context, a trial of anticoagulants versus placebo in patients more than 60 years old who had their previous myocardial infarction a median of 6 years before showed about a 50% reduction over 2 years in recurrent myocardial infarction and total mortality in the treated group.[22] The greater benefit shown in this study compared with the previous studies may be partly explained on the grounds that this was a stable group of patients in whom coronary thrombosis, potentially preventable by antithrombotic therapy rather than myocardial dysfunction, may have dictated the long-term prognosis.

The third possibility that may explain the lack of a more striking beneficial effect of aspirin may be related to a heterogeneity of mechanisms leading to rethrombosis in patients who have experienced a myocardial infarction. Aspirin only blocks platelet aggregation resulting from the activation of the prostaglandin system. It does not block platelet aggregation and fibrin formation resulting from other mechanisms, for example, adenosine diphosphate or the generation of thrombin.

Unstable angina and bypass graft patency trials: In contrast to the population recruited in the secondary prevention trials, patients with unstable angina do have a higher event rate for myocardial infarction and ischemic sudden death, and such events are most likely specifically thrombotic. In fact, 2 major, multicenter, double-blind, placebo-controlled trials of aspirin therapy in patients with unstable angina have been conducted and both showed a significant beneficial effect of therapy. In the Veterans Administration Cooperative Study[23] aspirin treatment (324 mg in buffered solution daily) for 12 weeks was tested in 1,266 men with unstable angina. The incidence of acute myocardial infarction or death was 51% lower in the aspirin-treated group (5%), compared with the placebo group (10%). The Canadian Multicenter Trial[24] used a higher dose of aspirin (325 mg 4 times daily) and observed their patients over a mean follow-up period of 18 months. The incidence of either nonfatal acute myocardial infarction or death was also 51% lower for patients treated with aspirin (9%), compared with those not given aspirin (17%).

Another area where platelet deposition and mural thrombus formation clearly play a crucial role is the occlusion of aortocoronary artery vein grafts. Chesebro et al[25] have demonstrated that therapy with dipyridamole, started 2 days before surgery and given on the morning of the operation and 1 hour after the procedure, plus aspirin (325 mg 3 times daily) added 7 hours after the operation, is highly effective in improving early postoperative vein graft patency. Moreover, this combined treatment appears to be of continued benefit 1 year after the operation.[26] More recent studies by Lorenz,[27] Goldman[28] and their co-workers have shown that a daily dose of only 100 mg or 325 mg of aspirin, respectively, significantly reduced aortocoronary bypass vein graft occlusion. Based on these recent aspirin trials in patients with coronary disease, the potential benefits of aspirin, even at a low dose, are beginning to emerge.

Primary Prevention Trials

Preliminary results from a double-blinded controlled trial in 22,000 male U.S. physicians assigned to receive buffered aspirin (325 mg every other day) or placebo for 5 years revealed a significant reduction in myocardial infarction from approximately 0.4% to 0.2% per year.[29] In advising the wide use of aspirin for primary prevention to apparently normal people there are 3 concerns: (1) the incidence of hemorrhagic stroke was slightly increased in the aspirin group; (2) a randomized primary prevention British study that involved 5,000 doctors taking aspirin 500 mg daily or placebo found no significant reduction in myocardial infarction but an increase in disabling stroke[30]; and (3) the very long-term effects of aspirin in blocking the prostaglandin metabolic pathway in various tissues (i.e., central nervous system) is unknown. Therefore, in our view aspirin should only be advised for primary prevention to individuals at very high risk for coronary disease, perhaps with the exclusion of hypertension because of increased risk of hemorrhagic stroke.

Ideal Dose of Aspirin

Primary inhibitors of the cyclooxygenase enzyme, such as aspirin, when given in a large dose, might inhibit not only platelet production of thromboxane A_2 and thereby platelet activation and aggregation, but also vessel wall synthesis of prostacyclin, an inhibitor of platelet aggregation.[31] Therefore, concerns have been raised regarding the possibility of attenuation of the platelet inhibitory effect by high aspirin dosage, or even its potential thrombogenicity. Such concerns have been overestimated. Epidemiologic studies of patients with rheumatoid arthritis treated with a very large dose of aspirin have not demonstrated an increase in thrombosis or atherosclerosis; this suggests that even high doses of aspirin are not thrombogenic in man.[32]

While high dose aspirin therapy may not enhance thrombogenicity, it is becoming more apparent that lower dose aspirin may be sufficient to achieve the desired antithrombotic benefit without significant side effects (gastrointestinal manifestations). Experimental demonstration that low dose (<1.0 mg/kg daily) aspirin was a selective and adequate inhibitor of thromboxane A_2-related platelet function[33] was quickly corroborated by observing clinical benefit from low dose regimens. As already noted, beneficial results were obtained with use of a relatively low dose of aspirin by the Veterans Administration study on unstable angina,[23] the Veterans Administration study on bypass graft patency[28] and the study of Lorenz et al.[27] Further, a recent clinical trial has shown clinical benefit (reduction in the incidence of hypertension and preeclampsia), with aspirin doses of 60 mg daily.[34]

All of these studies favoring low dose aspirin are important because if antithrombotic effects can be achieved with a minimal dose of the drug, the toxic side effects associated with higher dosages will be avoided. The side effects of aspirin are mainly gastrointestinal and dose related. Based on several trials using aspirin (900 mg daily or greater) in coronary artery disease,[15-20,24] the main side effects were stomach pain, heart burn, nausea and constipation, occult gastrointestinal blood loss and in a small percentage of patients, hematemesis and melena. In contrast, with low dose aspirin versus placebo, the Veterans Administration Cooperative Study on unstable angina[23] (aspirin 324 mg daily) showed "no significant differences in the incidence of epigastric burning or discomfort, decreased hemoglobin concentration, or occult blood in the stool."

It may also be argued that very low dose aspirin (<1 mg/kg) is preferable because previous studies suggested that lower doses may not inhibit vascular synthesis of prostacyclin.[33] The clinical relevance of selective inhibition of platelet cyclooxygenase, however, is doubtful. A recent study assessing local synthesis of prostacyclin after vessel injury failed to observe selective inhibition of platelet versus endothelial cyclooxygenase after 35 mg daily of aspirin.[35] Further, vessel walls diseased by atherosclerosis (the usual site of acute thrombotic activity) may not have normal endothelial surfaces that are capable of synthesizing prostacyclin. Finally, if very low doses of aspirin are used in the future, studies need to be done that prove that they are adequately absorbed by 100% of the patient population.

Based on these observations, we recommend 325 mg as the current therapeutic dose for aspirin. Doses between 60 and 325 mg will possibly be recommended in the near future based on clinical trials currently underway. Lastly, trials also need to be done to assess the clinical efficacy of aspirin doses <60 mg.

Platelet Physiology and Implications for Future Trials

Aspirin irreversibly acetylates the enzyme cyclooxygenase, thereby inhibiting thromboxane A_2 synthesis. Thromboxane A_2 activates the surface membrane of nearby platelets increasing their intracytoplasmic calcium and promoting more platelet aggregation. Besides being a potent inducer of irreversible platelet aggregation, thromboxane A_2 also constricts vascular smooth muscle. Thus, the beneficial effects of aspirin in unstable angina might be theoretically related to prevention of platelet aggregation and subsequent vascular occlusion, to prevention of vasopasm or to both. However, there may be other triggers leading to thrombotic-related myocardial infarction or death. In fact, aspirin-exposed platelets can still display a full aggregatory reaction in response to stimuli such as fibrillar collagen, adenosine diphosphate or thrombin, despite total suppression of thromboxane A_2 synthesis. Further, surface interactions between platelets and vessel wall, von Willebrands factor and fibrinogen may take place independently of thromboxane A_2.[36] Failure to fully appreciate such heterogeneity of mechanisms leading to platelet aggregation and thrombosis and aspirin's limited point of attack can lead to overestimating its therapeutic potential. Indeed, in the Veterans Administration Cooperative Study[23] and the Canadian Multicenter Trial[24] on unstable angina, the rate of transmural infarction or death was 5 and 9%, respectively. What remains to be established is whether the use of a more aggressive antithrombotic regimen, such as combination therapy with aspirin plus an anticoagulant, may result in an even lower morbidity, mortality and medical failure rate.

Therapy with aspirin plus an anticoagulant has been used in 3 previous trials in patients with prosthetic heart valves.[37-39] Two trials showed that combination therapy was more efficacious in reducing thromboembolism.[38,39] Combination therapy has also been tested in recent experimental work in the pig model using carotid artery injury induced by balloon angioplasty.[40] In this model, heparin (1 mg/kg daily) was effective in reducing thrombus formation, but the combination of aspirin plus heparin was substantially more effective.

It might be anticipated that the combination of aspirin with anticoagulants would produce more adverse effects than either drug alone. In fact, studies using ≥0.5 g of aspirin a day in combination with warfarin anticoagulation resulted in an excess of gastrointestinal bleeding complications.[39] It is possible, however, that the use of low dose aspirin (≤60 mg), which would be less likely to cause local gastric irritation, may be safely combined with warfarin therapy. The potential impact of a safe combination regimen in patients with coronary artery disease should be determined in future clinical trials.

To avoid many of
the serious toxicities
of antiarrhythmics...
Guide your patients
to safety

Guide them to MEXITIL® (MEXILETINE HCl)

The uncompromising efficacy of a first-line agent

MEXITIL is as effective as quinidine, procainamide, disopyramide, and tocainide in controlling ventricular arrhythmias including PVCs, couplets, and V Tach.[1-6]

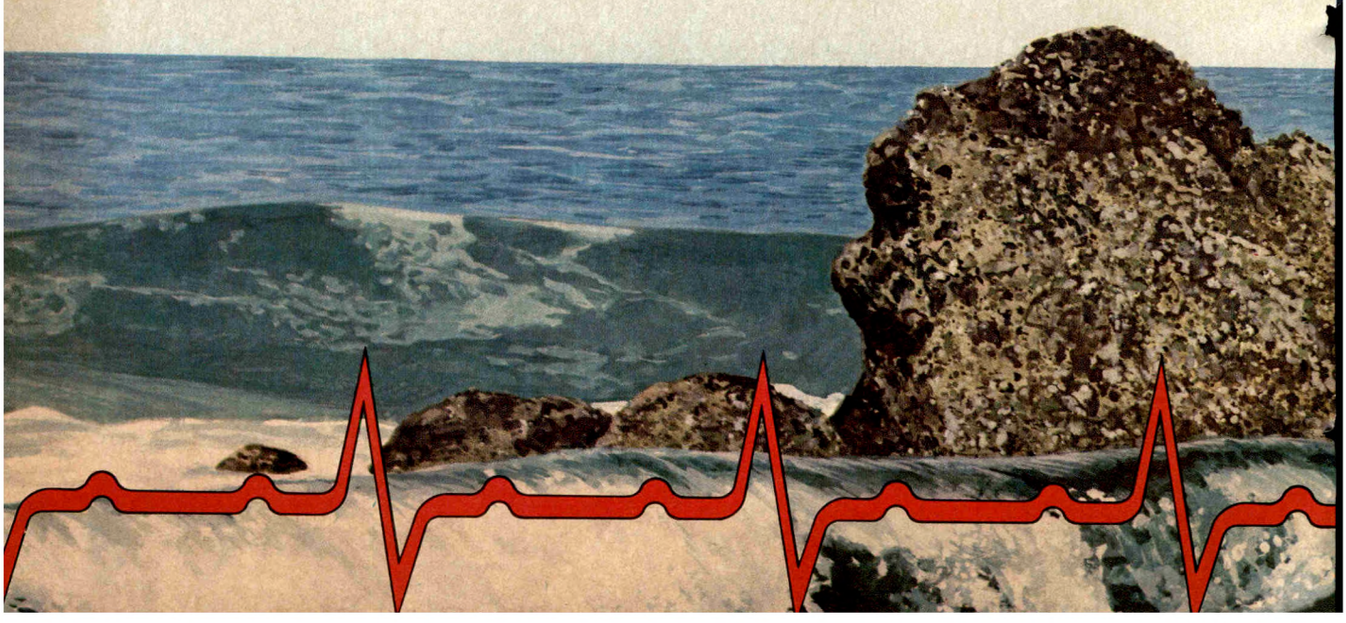
Avoids many late-onset toxicities encountered with other antiarrhythmics

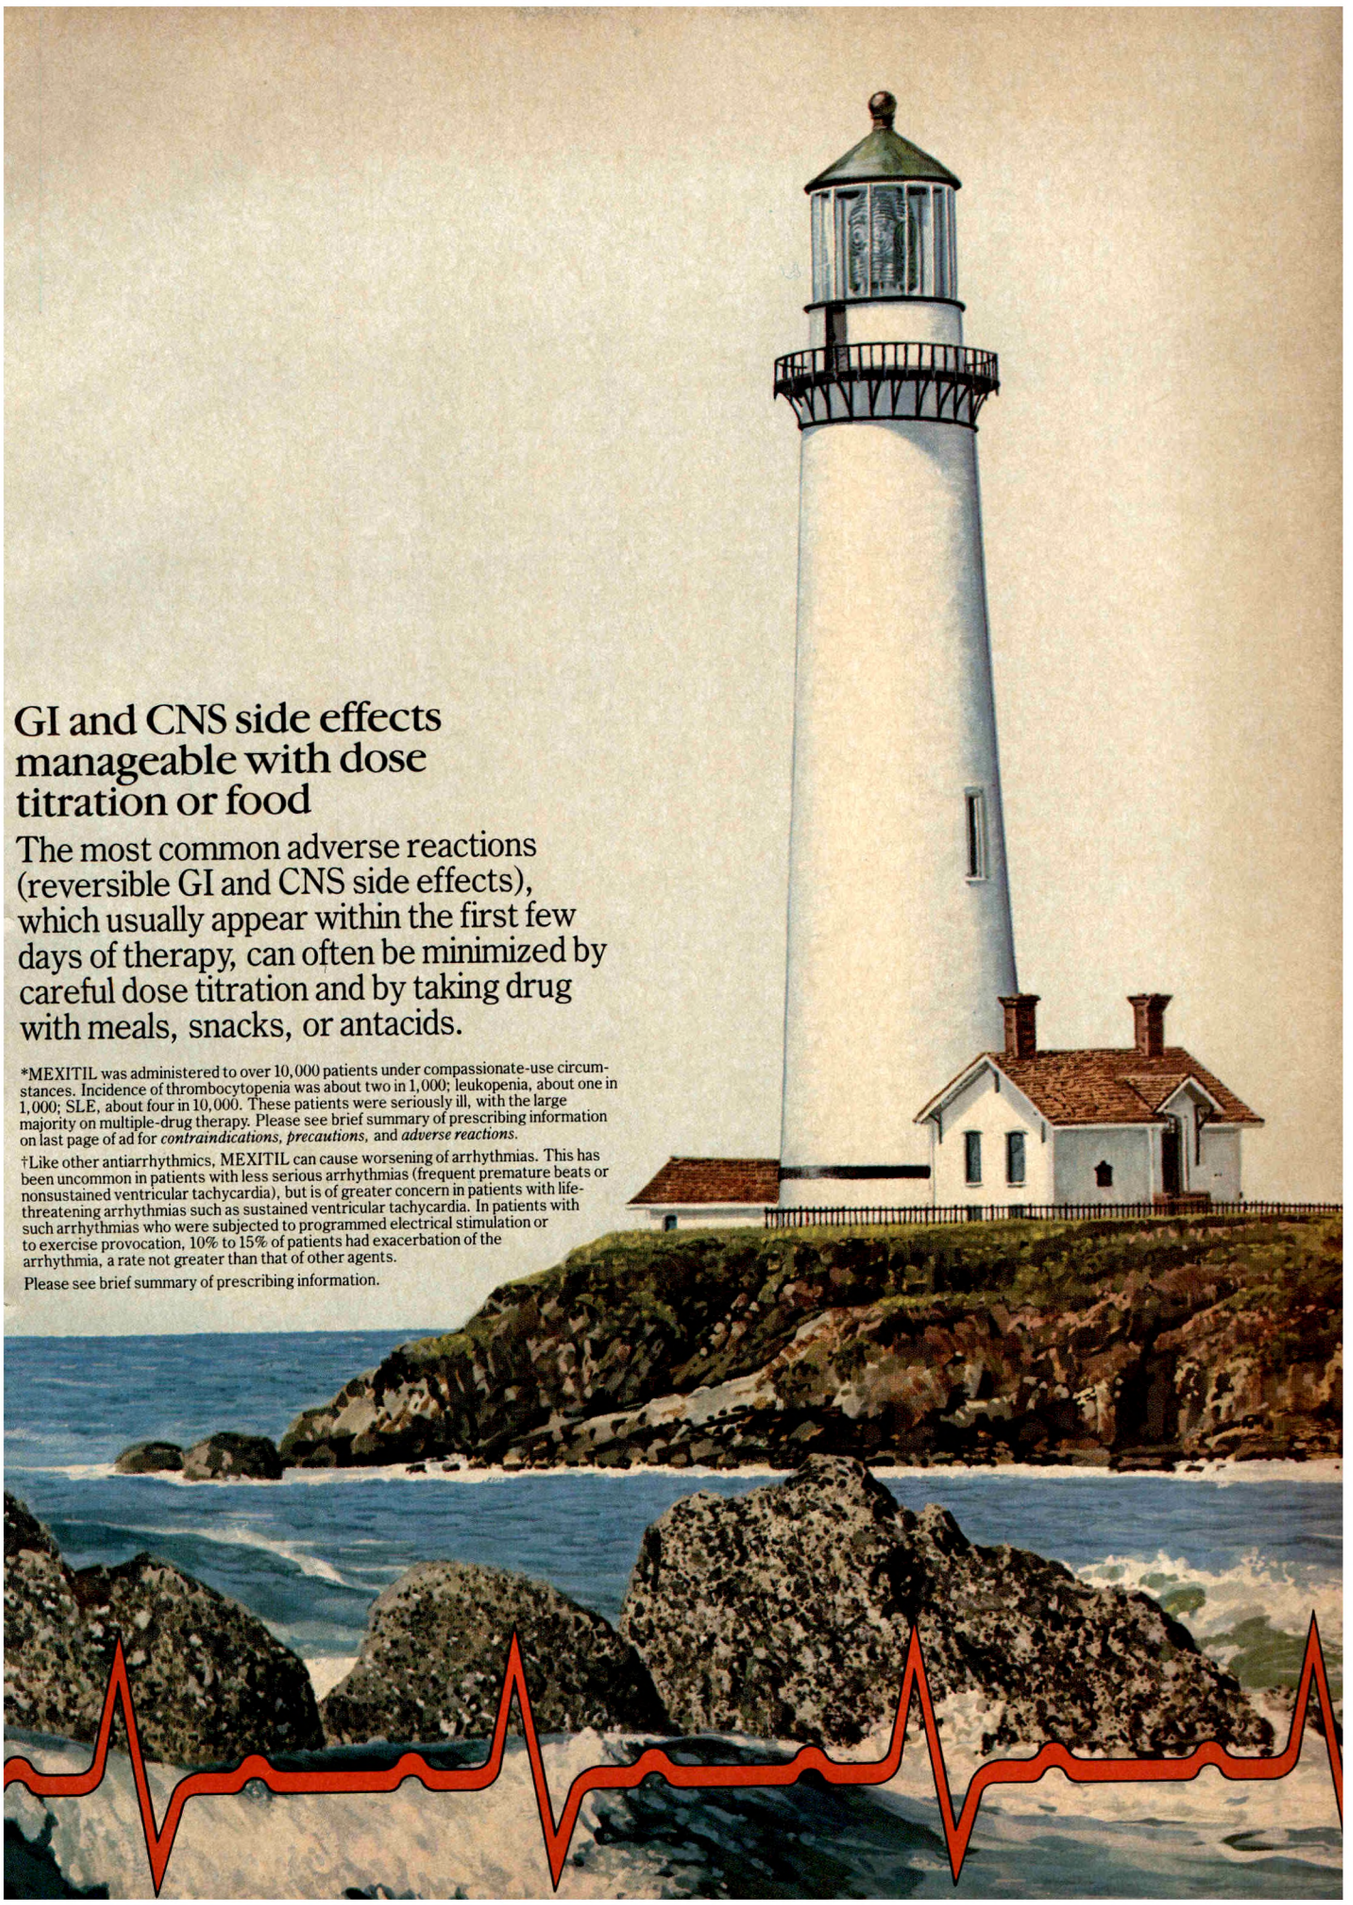
In controlled clinical trials, MEXITIL has not been associated with serious, late-onset toxicities such as hematologic effects, SLE, or pulmonary fibrosis.*

A favorable electrophysiologic and hemodynamic profile

MEXITIL is unlikely to aggravate arrhythmias in the clinical setting.[7-9†] It does not prolong the QT interval and, thus, is less likely than many other antiarrhythmics to produce torsades de pointes.[10,11]

MEXITIL has no significant negative inotropic effect, making it an excellent choice for use in patients with compromised cardiac function.[12-15]





GI and CNS side effects manageable with dose titration or food

The most common adverse reactions (reversible GI and CNS side effects), which usually appear within the first few days of therapy, can often be minimized by careful dose titration and by taking drug with meals, snacks, or antacids.

*MEXITIL was administered to over 10,000 patients under compassionate-use circumstances. Incidence of thrombocytopenia was about two in 1,000; leukopenia, about one in 1,000; SLE, about four in 10,000. These patients were seriously ill, with the large majority on multiple-drug therapy. Please see brief summary of prescribing information on last page of ad for *contraindications, precautions,* and *adverse reactions.*

†Like other antiarrhythmics, MEXITIL can cause worsening of arrhythmias. This has been uncommon in patients with less serious arrhythmias (frequent premature beats or nonsustained ventricular tachycardia), but is of greater concern in patients with life-threatening arrhythmias such as sustained ventricular tachycardia. In patients with such arrhythmias who were subjected to programmed electrical stimulation or to exercise provocation, 10% to 15% of patients had exacerbation of the arrhythmia, a rate not greater than that of other agents.

Please see brief summary of prescribing information.

MEXITIL®
(MEXILETINE HCl)

Distinguished by Its Safety Profile

Mexitil®
(mexiletine hydrochloride)
Oral Antiarrhythmic

Capsules of 150 mg, 200 mg and 250 mg

Brief Summary of Prescribing Information

CONTRAINDICATIONS: Mexitil® (mexiletine hydrochloride) is contraindicated in the presence of cardiogenic shock or pre-existing second- or third-degree AV block (if no pacemaker is present).

PRECAUTIONS: General: If a ventricular pacemaker is operative, patients with second or third degree heart block may be treated with Mexitil® (mexiletine hydrochloride) if continuously monitored. A limited number of patients (45 of 475 in controlled clinical trials) with pre-existing first degree AV block were treated with Mexitil; none of these patients developed second or third degree AV block. Caution should be exercised when it is used in such patients or in patients with pre-existing sinus node dysfunction or intraventricular conduction abnormalities.

Like other antiarrhythmics Mexitil can cause worsening of arrhythmias. This has been uncommon in patients with less serious arrhythmias (frequent premature beats or non-sustained ventricular tachycardia: see ADVERSE REACTIONS), but is of greater concern in patients with life-threatening arrhythmias such as sustained ventricular tachycardia. In patients with such arrhythmias subjected to programmed electrical stimulation or to exercise provocation, 10-15% of patients had exacerbation of the arrhythmia, a rate not greater than that of other agents.

Mexitil should be used with caution in patients with hypotension and severe congestive heart failure. Since Mexitil is metabolized in the liver, and hepatic impairment has been reported to prolong the elimination half-life of Mexitil, patients with liver disease should be followed carefully while receiving Mexitil. The same caution should be observed in patients with hepatic dysfunction secondary to congestive heart failure.

Concurrent drug therapy or dietary regimens which may markedly alter urinary pH should be avoided during Mexitil therapy. The minor fluctuations in urinary pH associated with normal diet do not affect the excretion of Mexitil.

SGOT Elevation and Liver Injury: In three-month controlled trials, elevations of SGOT greater than three times the upper limit of normal occurred in about 1% of both mexiletine-treated and control patients. Approximately 2% of patients in the mexiletine compassionate use program had elevations of SGOT greater than or equal to three times the upper limit of normal. These elevations frequently occurred in association with identifiable clinical events and therapeutic measures such as congestive heart failure, acute myocardial infarction, blood transfusions and other medications. These elevations were often asymptomatic and transient, usually not associated with elevated bilirubin levels and usually did not require discontinuation of therapy. Marked elevations of SGOT (>1000 U/L) were seen before death in four patients with end-stage cardiac disease (severe congestive heart failure, cardiogenic shock).

In foreign marketing experience rare instances of severe liver injury, including hepatic necrosis, have been reported in association with Mexitil treatment. It is recommended that patients in whom an abnormal liver test has occurred, or who have signs or symptoms suggesting liver dysfunction, be carefully evaluated. If persistent or worsening elevation of hepatic enzymes is detected, consideration should be given to discontinuing therapy.

Blood Dyscrasias: Blood dyscrasias were not seen in the controlled trials. Among 10,867 patients treated with mexiletine in the compassionate use program, marked leukopenia (neutrophils less than 1000/mm^3) or agranulocytosis were seen in 0.06%, and milder depressions of leukocytes were seen in 0.08%, and thrombocytopenia was observed in 0.16%. Many of these patients were seriously ill and receiving concomitant medications with known hematologic adverse effects. Rechallenge with mexiletine in several cases was negative. Marked leukopenia or agranulocytosis did not occur in any patient receiving Mexitil alone; five of the six cases of agranulocytosis were associated with procainamide (sustained release preparations in four) and one with vinblastine. If significant hematologic changes are observed, the patient should be carefully evaluated, and, if warranted, Mexitil should be discontinued. Blood counts usually return to normal within one month of discontinuation. (See ADVERSE REACTIONS.)

Convulsions (seizures) did not occur in Mexitil controlled clinical trials. In the compassionate use program, convulsions were reported in about 2 of 1000 patients. Twenty-eight percent of these patients discontinued therapy. Convulsions were reported in patients with and without a prior history of seizures. Mexiletine should be used with caution in patients with known seizure disorder.

Drug Interactions: In a large compassionate use program Mexitil has been used concurrently with commonly employed antianginal, antihypertensive, and anticoagulant drugs without observed interactions. A variety of antiarrhythmics such as quinidine or propranolol were also added, sometimes with improved control of ventricular ectopy. When phenytoin or other hepatic enzyme inducers such as rifampin and phenobarbital have been taken concurrently with Mexitil, lowered Mexitil plasma levels have been reported. Monitoring of Mexitil plasma levels is recommended during such concurrent use to avoid ineffective therapy.

In a formal study, benzodiazepines were shown not to affect Mexitil plasma concentrations. ECG intervals (PR, QRS and QT) were not affected by concurrent Mexitil and digoxin, diuretics, or propranolol.

Concurrent administration of cimetidine and Mexitil has been reported to increase, decrease, or leave unchanged Mexitil plasma levels; therefore patients should be followed carefully during concurrent therapy.

Mexitil does not alter serum digoxin levels, but magnesium-aluminum hydroxide, when used to treat gastrointestinal symptoms due to Mexitil, has been reported to lower serum digoxin levels.

Carcinogenesis, Mutagenesis and Impairment of Fertility: Studies of carcinogenesis in rats (24 months) and mice (18 months) did not demonstrate any tumorigenic potential. Mexitil was found to be non-mutagenic in the Ames test. Mexitil did not impair fertility in the rat.

Pregnancy/Teratogenic Effects

Pregnancy Category C: Reproduction studies performed with Mexitil in rats, mice and rabbits at doses up to four times the maximum human oral dose (20 mg/kg in a 50 kg patient) revealed no evidence of teratogenicity or impaired fertility but did show an increase in fetal resorption. There are no adequate and well-controlled studies in pregnant women; this drug should be used in pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Mexitil appears in human milk in concentrations similar to those observed in plasma. Therefore, if the use of Mexitil is deemed essential, an alternative method of infant feeding should be considered.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Mexitil® (mexiletine hydrochloride) commonly produces reversible gastrointestinal and nervous system adverse reactions but is otherwise well tolerated. Mexitil has been evaluated in 483 patients in one-month and three-month controlled studies and in over 10,000 patients in a large compassionate use program. Dosages in the controlled studies ranged from 600-1200 mg/day; some patients (8%) in the compassionate use program were treated with higher daily doses (1600-3200 mg/day). In the three-month controlled trials comparing Mexitil to quinidine, procainamide and disopyramide, the most frequent adverse reactions were upper gastrointestinal distress (41%), lightheadedness (10.5%), tremor (12.6%) and coordination difficulties (10.2%). Similar frequency and incidence were observed in the one-month placebo-controlled trial. Although these reactions were generally not serious, and were dose-related and reversible with a reduction in dosage, by taking the drug with food or antacid or by therapy discontinuation, they led to therapy discontinuation in 40% of patients in the controlled trials. A tabulation of the adverse events reported in the one-month placebo-controlled trial follows:

Comparative Incidence (%) of Adverse Events among Patients Treated with Mexiletine and Placebo in the 4-Week, Double-Blind Crossover Trial

	Mexiletine N=53	Placebo N=49
Cardiovascular		
Palpitations	7.5	10.2
Chest Pain	7.5	4.1

Less than 1%: Syncope, edema, hot flashes, hypertension, short-term memory loss, loss of consciousness, other psychological changes, diaphoresis, urinary hesitancy/retention, malaise, impotence/decreased libido, pharyngitis.

An additional group of over 10,000 patients has been treated in a program allowing administration of Mexitil under compassionate use circumstances. These patients were seriously ill with the large majority on multiple drug therapy. Twenty-four percent of the patients continued in the program for one year or longer. Adverse reactions leading to therapy discontinuation occurred in 15% of patients (usually upper gastrointestinal system or nervous system effects). In general, the more common adverse reactions were similar to those in the controlled trials. Less common adverse events possibly related to Mexitil use include:

Cardiovascular System: Syncope and hypotension, each about 6 in 1000; bradycardia, about 4 in 1000; angina/angina-like pain, about 3 in 1000; edema, atrioventricular block/conduction disturbances and hot flashes, each about 2 in 1000; atrial arrhythmias, hypertension and cardiogenic shock, each about 1 in 1000.

Central Nervous System: Short-term memory loss, about 9 in 1000 patients; hallucinations and other psychological changes, each about 3 in 1000; psychosis and convulsions/seizures, each about 2 in 1000; loss of consciousness, about 6 in 10,000.

Digestive: Dysphagia, about 2 in 1000; peptic ulcer, about 8 in 10,000; upper gastrointestinal bleeding, about 7 in 10,000; esophageal ulceration, about 1 in 10,000.

Laboratory: Abnormal liver function tests, about 5 in 1000 patients; positive ANA and thrombocytopenia, each about 2 in 1000; leukopenia (including neutropenia and agranulocytosis), about 1 in 1000; myelofibrosis, about 2 in 10,000 patients.

Other: Diaphoresis, about 6 in 1000; altered taste, about 5 in 1000; salivary changes, hair loss and impotence/decreased libido, each about 4 in 1000; malaise, about 3 in 1000; urinary hesitancy/retention, each about 2 in 1000; hiccups, dry skin, laryngeal and pharyngeal changes and changes in oral mucous membranes, each about 1 in 1000; SLE syndrome, about 4 in 10,000.

Hematology: Blood dyscrasias were not seen in the controlled trials but did occur among the 10,867 patients treated with mexiletine in the compassionate use program: (See PRECAUTIONS). Myelofibrosis was reported in two patients in the compassionate use program; one was receiving long-term thiotepa therapy and the other had pretreatment myeloid abnormalities.

HOW SUPPLIED:
Mexitil® (mexiletine hydrochloride) is supplied in hard gelatin capsules containing 150, 200 or 250 mg of mexiletine hydrochloride in bottles of 100 and individually blister-sealed unit-dose cartons of 100.

Consult package insert before prescribing.

Coronary Artery Disease in Women

ELAINE D. EAKER, ScD, BARBARA PACKARD, MD, PhD, NANETTE K. WENGER, MD, THOMAS B. CLARKSON, DVM, and H.A. TYROLER, MD

Diseases of the heart are the leading cause of death among women in the U.S. and account for about 28% of all deaths in women. Of the 550,000 people who die each year in the U.S. from heart-related diseases, >250,000 are women. Because coronary artery disease (CAD) is less common in women, it has not been as thoroughly studied in women as in men. Results from studies of men have frequently been generalized to women, which may not be appropriate.

The National Heart, Lung, and Blood Institute Workshop on Coronary Heart Disease in Women, held in Bethesda, Maryland, January 26 to 28, 1986, convened scientists from the disciplines of epidemiology, atherosclerosis and clinical cardiology who have studied or have access to data about CAD in women. The workshop was designed to delineate the current state of knowledge about CAD in women and to define issues and questions that need further study, areas where information is lacking and needs and opportunities for research. Three aspects of CAD in women were discussed: (1) epidemiologic data on the prevalence and risk of fatal and nonfatal CAD, (2) pathophysiologic processes of atherogenesis that may be unique to women and (3) clinical aspects of CAD in women. The following is a summary of the workshop deliberations in each of these areas.

Epidemiologic Data: Fatal and Nonfatal Coronary Artery Disease in Women

Of the 250,000 women who die from CAD each year in the U.S. 100,000 of these deaths are premature (before average age of life expectancy). Although CAD is the leading cause of death in both black and white U.S. women, black women have a higher CAD mortality rate, especially in the younger age groups.

From the National Heart, Lung, and Blood Institute, Bethesda, Maryland, Emory University, Atlanta, Georgia, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, and the University of North Carolina, Chapel Hill, North Carolina. Manuscript received October 15, 1987; revised manuscript received and accepted November 6, 1987.

Address for reprints: Elaine D. Eaker, ScD, Epidemiology and Biometry Program National Heart, Lung, and Blood Institute, Federal Building, Room 2c08, Bethesda, Maryland 20892.

The 37% decrease in CAD mortality between 1963 and 1983 was similar for men and women. From 1968 to 1978 the percent of decrease in CAD mortality was greater among women that men, but the reverse was true from 1979 to 1983. Black women had the greatest rate of decrease in CAD mortality of any sex-race group from 1968 to 1978, but the smallest rate of decrease from 1979 to 1983. Despite this consistent decrease in the CAD death rates, marked geographic differences are evident. Clusters of high CAD death rate areas for women as well as men are present in the mid-Atlantic states of New York, New Jersey, Pennsylvania, Ohio, Kentucky and West Virginia; the western mountain states have the lowest quartile of CAD death rates in women. There is a wide range in international CAD death rates among women aged 40 to 69 years. In Scotland and Ireland the rates for 1980 were approximately 200/100,000, whereas in France and Japan the rates were about 25/100,000. However, a consistent trend of decreasing CAD death rates in women between 1950 and 1978 is present in industrialized countries.

Although U.S. women experience less than half the age-adjusted mortality rate from CAD as men, women generated 58% of total expenditures for heart disease—$7.6 billion in 1980. Women, in general, recognize and report systemic hypertension more often than men, although the prevalence of hypertension is greater among men through 55 years of age. Black women have a greater prevalence of hypertension than do white women, and report seeking care more frequently. Reports of all cardiovascular diseases were greater among women than would be expected from epidemiologic studies, indicating a greater awareness of these diseases by women. In addition, women reported cardiovascular disease as a problem as often as or more frequently than men. Women make more ambulatory care visits for cardiovascular diseases than do men; however, hospital admission rates do not differ by gender. Women receive more medical attention for cardiovascular diseases than do men. They also generally report more restricted activity than men, but no greater inability to work due to cardiovascular disease.

The potential risk factors for CAD in women can be divided into characteristics shared by both women and

men (e.g., increased age, systemic hypertension, cigarette smoking, levels of certain plasma lipoproteins, diabetes mellitus and obesity) and those pertinent only to women (e.g., oral contraceptive use, menopause, hysterectomy and exogenous hormone use). Estimates of the levels and distributions of coronary risk factors in the U.S. are available from surveys of the National Center of Health Statistics. Based on the National Health and Nutrition Examination Survey II (1976 to 1980), 25% of white women and 38% of black women aged 18 to 74 years have hypertension (defined as systolic blood pressure ≥140 mm Hg, or diastolic blood pressure ≥90 mm Hg, and also including women taking blood pressure medication). In the late 1970s, about one-fourth of all white women aged 25 to 74 years had high risk serum cholesterol levels (defined as >220 mg/dl for women aged 20 to 29, >240 for women aged 30 to 39 and >260 for women aged 40+). In 1983, 29% of women 20 years of age and older were cigarette smokers. Women in this age group have only slightly decreased their cigarette smoking from 1965 to 1983. Among women aged 20 to 29 years, however, cigarette smoking has increased from 1980 to 1983.

Most evidence relating individual attributes to the development of CAD has been derived predominantly from analyses done in men. Many studies, however, also included data from women; multivariate analyses of these data showed that increased age, cigarette smoking, systemic hypertension, diabetes mellitus or glucose intolerance contributed to the risk of CAD in women. Elevated total and low density lipoprotein cholesterol levels are strong coronary risk factors and elevated high density lipoprotein cholesterol appears to be protective against CAD. Other factors that appeared in some studies to be associated with myocardial infarction or CAD in women include blood group A, family history of myocardial infarction, history of previous heart disease, chest pain, blood pressure medication and elevated triglyceride levels. Physical activity, vital capacity and social group membership are, in some studies, inversely related to CAD risk in women. Diabetes mellitus imparts a greater risk to women compared with men when the other risk factors are taken into account.

For characteristics unique to women, most studies indicate a 3- to 4-fold increase in risk of both fatal and nonfatal myocardial infarction in women using oral contraceptives; this risk increases among heavy cigarette smokers. The risk of myocardial infarction among past users of oral contraceptives appears similar to that of women who never used oral contraceptives.

The effect of menopausal status on CAD risk is unclear. Before natural menopause, CAD rates are very low, but increase rapidly with menopause. Little evidence exists, however, that menopause per se or the attendant changes in hormones and lipids are responsible for the increased occurrence of CAD. The coronary risk associated with menopause is confounded by such variables as age of onset of menopause, natural versus surgical menopause and changing use of exogenous hormones. Most data indicate a protective association against CAD risk for use of noncontraceptive hormones in postmenopausal women; however, some studies show no effect or a detrimental association. The relation of reproductive status to CAD or atherosclerosis in women also remains unclear.

Most studies do not include data on psychosocial and behavior characteristics of women. Those studies with psychosocial information showed that lack of group membership was related to CAD mortality in women and that type A behavior was related to manifestations of CAD when angina pectoris was present.

Pathophysiologic Processes of Atherogenesis

In studies of human atherosclerosis, women of certain races and societies have substantially less CAD and coronary artery atherosclerosis during their reproductive years than do their male counterparts. White women have significantly fewer diseased coronary arteries than do black women.

Nonhuman primates, such as cynomolgus macaques, have been used as animal models to study atherosclerosis because they are similar to humans in gender differences regarding the extent of coronary artery atherosclerosis and gender differences in serum cholesterol concentrations. In addition, female cynomolgus macaques have a menstrual cycle similar to that of women. Ovarian function is a major factor associated with atherosclerosis in female cynomolgus macaques; ovarian function and concomitant endocrine function are markedly affected by social behavior, as subordinate macaque females often exhibit ovarian and endocrine deficiencies that are closely associated with atherosclerosis.

Interest has been growing in the relations among physical activity, lipid levels and CAD in women. Recent studies have shown that endurance training in women is associated with a decrease in circulating estrogen concentrations. The relation of exercise to high density lipoprotein cholesterol levels is inconsistent. The effects of exercise on plasma cholesterol and sex steroid concentrations have been studied in both pre- and postmenopausal women. Young women runners progressively increase their high density lipoprotein cholesterol concentration (independent of weight loss) and decrease their estrogen concentrations. Postmenopausal women have no significant changes in total plasma cholesterol, high density lipoprotein cholesterol or estrogen concentration after 8 months of exercise. Menopausal women do not appear to respond to exercise as do men and younger women; their level of exercise may not have been adequate to elicit a response or their low estrogen level may have rendered them insensitive to the effects of exercise on high density lipoprotein cholesterol.

Research scientists have speculated that cardiovascular and neuroendocrine hyperactivity to behavioral stimuli may be the biologic mechanism that predisposes individuals to coronary atherosclerosis. Women have significantly smaller epinephrine responses to common psychologic stressors than men do, but this

relation is largely behavioral in origin. When women are observed under stressful conditions that are personally "relevant" (in the sense that psychomotor and achievement-oriented tasks may be seen as relevant by men), women are as equally reactive as men. Some studies have shown more pronounced cardiovascular responses to stress in postmenopausal women, compared with age-matched premenopausal control subjects.

Because women are often prescribed hormonal steroids both for contraception and for menopausal symptoms, the effects of these hormonal steroids on lipoprotein levels and atherogenesis are of interest. The use of estrogen-progesterone oral contraceptives increases low density lipoprotein cholesterol levels; this increase varies with different preparations, particularly those containing higher hormone doses. Therapy with postmenopausal estrogens in "replacement" doses decreases both intermediate low density lipoprotein and low density lipoprotein levels; high density lipoprotein levels increase, particularly the high density lipoprotein$_2$ subfraction. There is little evidence that cyclic progestogen and estrogen use affects lipoprotein levels.

Clinical Aspects of Coronary Artery Disease in Women

Although CAD accounts for one-third of all deaths among women, evaluation of medical therapies for women with CAD has been limited. First coronary events are more often fatal in women (39%) than in men (31%). Excluding fatalities, the initial manifestations of CAD are strikingly dissimilar: 50% of men present with myocardial infarction compared with 34% of women. Angina pectoris is described as the initial manifestation of CAD in 55% of women compared with 43% of men. Angiographic studies demonstrate that fewer than 50% of women presenting with chest pain have coronary artery obstructive lesions, casting doubt on epidemiologic data based on chest pain (angina) history without angiographic confirmation or occurrence of a definite CAD event.

Studies of the relation of coronary artery atherosclerosis to chest pain in white men and women show that all subgroups of men with chest pain have a greater than 50% prevalence of coronary stenosis, whereas only those subgroups of women with Canadian Heart Association class III and IV angina have a majority with such stenoses. The lower prevalence of CAD in women and the equal or higher prevalence of noncardiac causes of chest pain lead to a high rate of false-positive diagnoses of CAD in women with chest pain. While the clinical manifestations of CAD are similar in men and women, the noninvasive diagnosis of CAD in women presents a major problem. The criteria for the diagnosis of CAD by various noninvasive procedures have been derived from populations of men and applied to women; however, the relatively low prevalence of CAD in women produces a higher ratio of false-positive to true-positive results.

Diagnostic outcome varies in women depending on their presenting symptoms. Women with definite classic angina pectoris have a high likelihood of underlying CAD. With probable angina pectoris, only about one-third of women will have CAD. Attempts have been made to improve the specificity and sensitivity of diagnostic exercise testing in women by using thallium myocardial imaging and radionuclide ventriculography. In the clinical evaluation of women with classic angina pectoris, the exercise electrocardiogram and cardiac fluoroscopy appear cost-effective in providing important diagnostic information that may preclude the need for further noninvasive testing in most patients. In women with probable angina pectoris, thallium exercise scintigraphy or cardiac fluoroscopy, or a combination of the 2, represent a better diagnostic choice than the exercise electrocardiogram alone, because of higher specificity with similar sensitivity.

The left ventricular mass and various indexes of it are significantly less in women than in men. When corrected for body mass, however, this difference disappears. Certain parameters of left ventricular function in women with CAD differ significantly from those of men with CAD. For example, the ejection fraction is significantly higher in women with CAD than in men with CAD. The effect of left ventricular dysfunction, however, on morbidity and mortality appears to be similar in men and women. The apparent better preoperative left ventricular function in women with CAD, however, does not translate into an improved outcome after coronary artery bypass graft surgery.

Post-infarction ventricular arrhythmias have been identified as important adverse prognostic characteristics in men. Data from the Multicenter Postinfarction Trial indicate that the significant association of frequent ventricular ectopy with 2-year mortality in men does not occur in women. In contrast, ejection fractions of <30% predicted mortality in both men and women.

Because women have a different endocrine response than men, their medication effects may differ. An important area of drug therapy with considerable data for women is antihypertensive therapy. Women describe more side effects from β-blocking drugs than do men. A possible explanation for the increased occurrence of side effects in women may be due to the fixed-dose therapy in most clinical trials. Women's reduced body mass may result in a relatively greater drug dose effect. Although women with hypertension live longer than hypertensive men, some studies have shown that antihypertensive therapy provides less benefit in preventing CAD among women, particularly white women compared with white men. This apparent reduced benefit is confounded by a number of factors, not the least of which is the lower overall morbidity and mortality from cardiovascular disease among women. Nevertheless, the same guidelines for the treatment of hypertension were considered appropriate for both men and women. Previous studies suggest that both short- and long-term effects of antihy-

pertensive therapy may differ in women; because the effectiveness varies for different cardiovascular endpoints (i.e., greater stroke benefit vs lesser CAD benefit), future studies should collect and analyze their data accordingly.

Both the efficacy and side effects of the 3 currently used classes of antianginal drugs—nitrates, β blockers and calcium antagonists—have been studied predominantly in men. Because women, in general, have smaller coronary arteries related to their smaller body size, fluctuations in coronary tone may be of increased importance. This suggests that nitrates and calcium antagonists may be preferred therapies. Nitrates and calcium antagonists are equally effective in treating patients with variant angina due to spasm.

From 1979 to 1984, the number of coronary artery bypass grafting procedures have more than doubled in women. Data from the Coronary Artery Surgery Study show that female sex predicted perioperative coronary artery bypass surgery mortality better than severity of angina or severity of left ventricular dysfunction. There were also large preoperative differences, such as body size, between men and women undergoing coronary artery bypass grafting that may have contributed to the differing outcomes. Women who survive the perioperative phase have a 5- and 10-year survival comparable to that of men, despite a lesser symptomatic improvement.

Percutaneous transluminal coronary angioplasty is a nonsurgical method of myocardial revascularization for selected patients with documented obstructive CAD. Short-term outcomes of this procedure in the early years, as documented in the Percutaneous Transluminal Coronary Angioplasty registry, indicated that female gender was an independent predictor of lower success and higher complication and mortality rates. This mortality difference is not evident in more recent series. In contrast to the less favorable short-term outcomes, after successful angioplasty women have comparable symptomatic improvement, a lower incidence of restenosis and need for revascularization and similar survival compared with men.

Following a myocardial infarction women are described as having more anxiety, depression and sexual dysfunction, and return to work less often than men. This raises the question of the effect of age on gender differences in response to a heart attack. Problems associated with widowhood, lack of social support, inadequate financial support and other concerns have not been systematically evaluated.

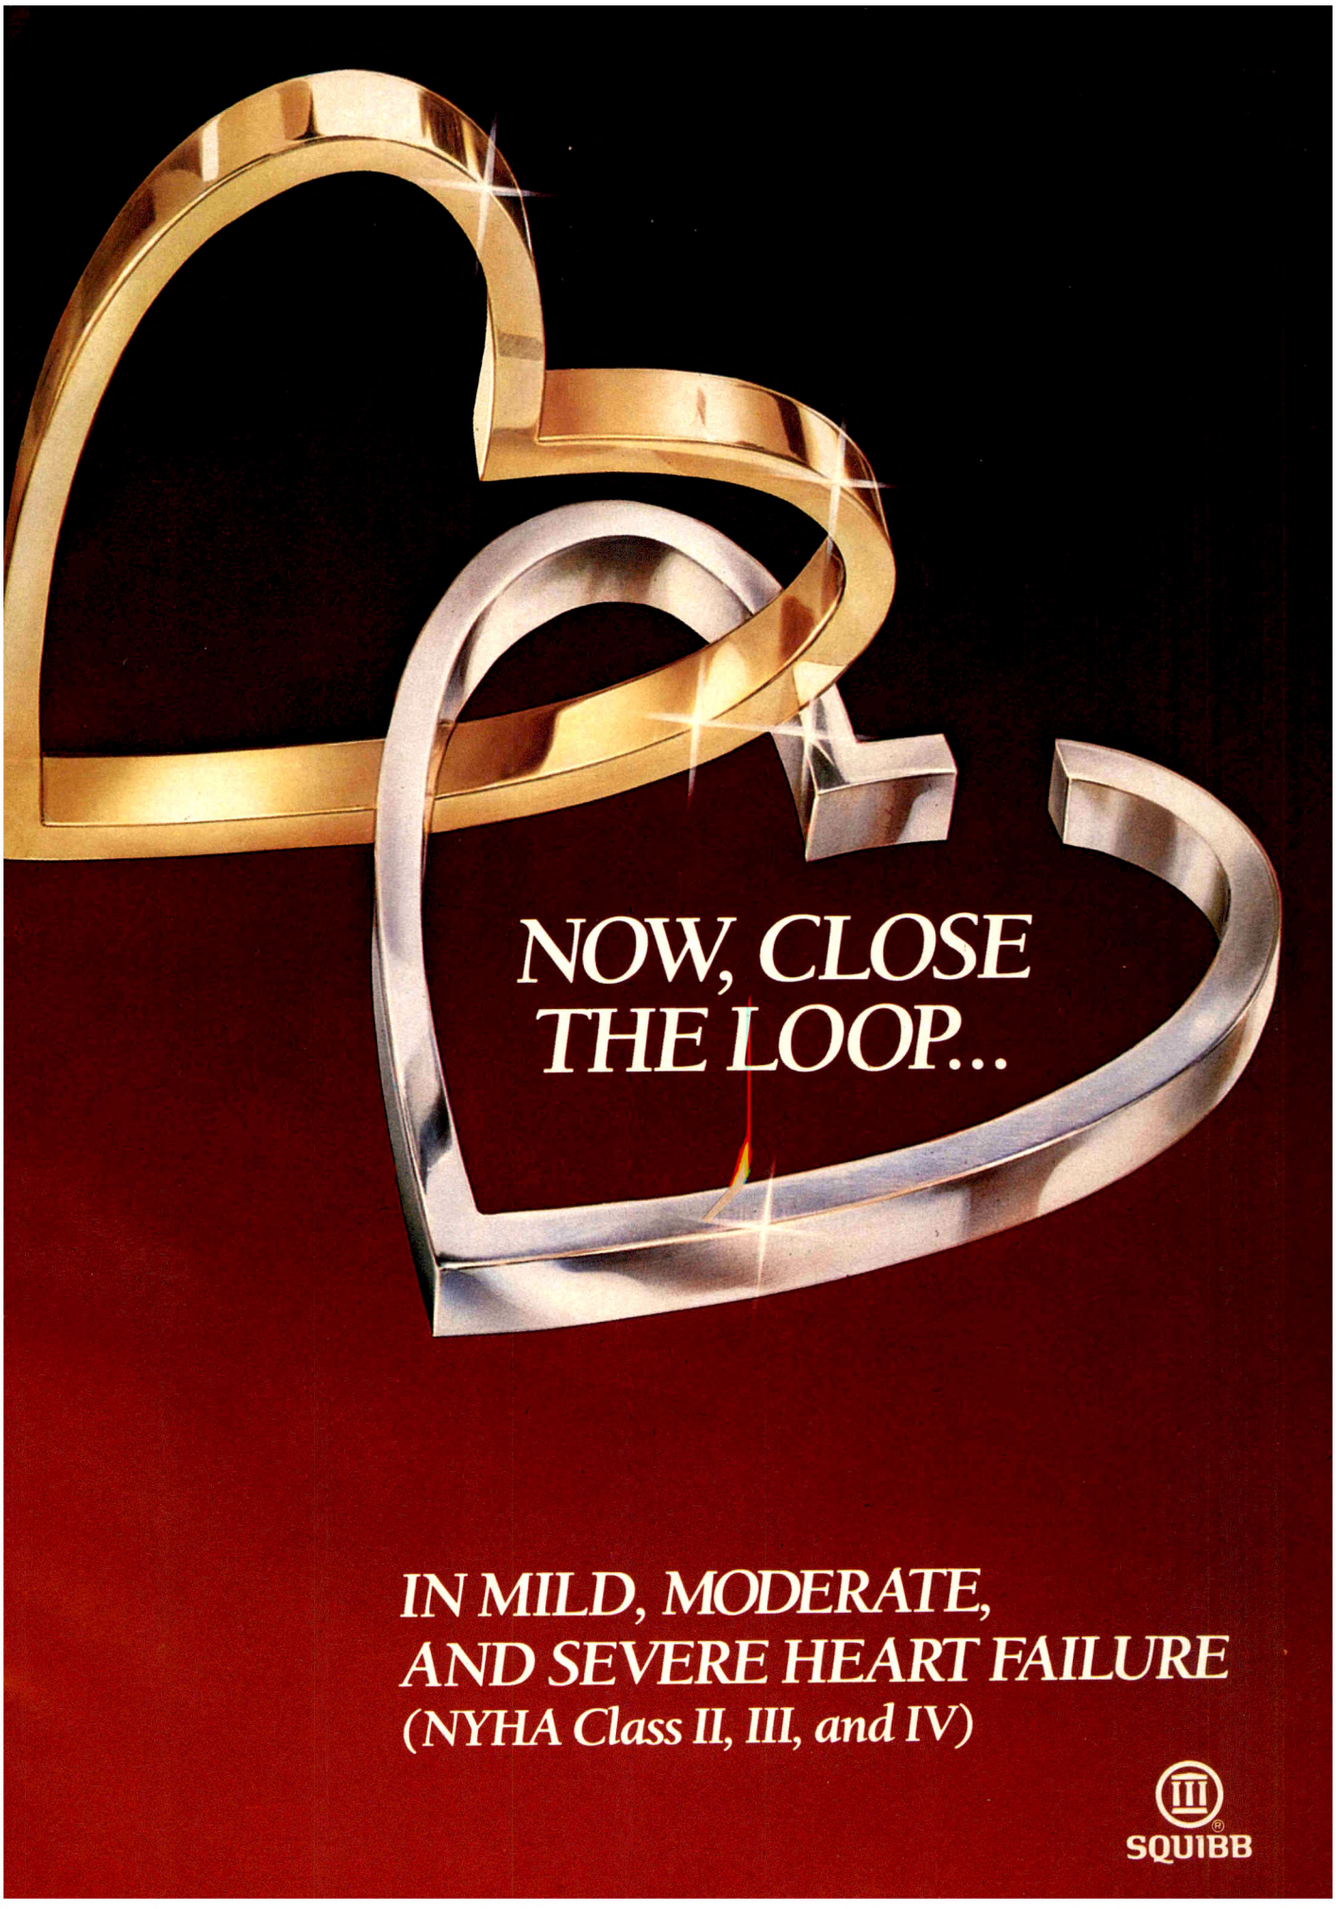
The National Heart, Lung, and Blood Institute Workshop on Coronary Heart Disease in Women

Organizing Committee: Thomas B. Clarkson, DVM, Bowman Gray School of Medicine, Wake Forest University; Elaine D. Eaker, ScD, National Heart, Lung, and Blood Institute; Barbara Packard, MD, PhD, National Heart, Lung, and Blood Institute; H. A. Tyroler, MD, University of North Carolina; and Nanette K. Wenger, MD, Emory University.

Participants: Michael R. Adams, DVM, Bowman Gray School of Medicine, Wake Forest University; Elizabeth Barrett-Connor, MD, University of California, San Diego; Martial Bourassa, MD, Montreal Heart Institute; Thomas W. Boyden, MD, VA Medical Center, Tucson; Katherine Detre, MD, PH, University of Pittsburgh; Frederick H. Epstein, MD, University of Zurich, Switzerland; Curt Furberg, MD, Bowman Gray School of Medicine, Wake Forest University; William R. Harlan, MD, University of Michigan; Michael V. Herman, MD, Westchester City Medical Center; Trudy L. Bush, PhD, Columbia University; William P. Castelli, MD, Framingham Heart Study, National Heart, Lung, and Blood Institute; Michael J. Cowley, MD, Medical College of Virginia; Kathryn Davis, PhD, University of Washington; Arthur J. Moss, MD, University of Rochester; William P. Newman, III, MD, Louisiana State University; Barbara L. Parry, MD, University of California, San Diego; Thomas A. Pearson, MD, PhD, Johns Hopkins University; Elliot Rapaport, MD, University of California, San Francisco; Millicent Higgins, MD, National Heart, Lung, and Blood Institute; Adolph M. Hutter, Jr., MD, Massachusetts General Hospital; William B. Kannel, MD, Boston University School of Medicine; Julian Keil, PH, Medical University of South Carolina; Luella Klein, MD, Emory University; Mary Grace Kovar, PH, National Center for Health Statistics; Ronald M. Krauss, MD, University of California, Berkeley; Paul E. Leaverton, PhD, University of South Florida; Stephen Manuck, PhD, University of Pittsburgh; Karen Matthews, PhD, University of Pittsburgh; Henry C. McGill, Jr., MD, University of Texas Health Science Center, San Antonia; Lois Monteiro, RN, PhD, Brown University; Robert Roberts, MD, Baylor College of Medicine; Lynn Rosenberg, ScD, Boston University; Stephen M. Schwartz, MD, PhD, University of Washington; Alvin P. Shapiro, MD, University of Pittsburgh; Meir J. Stampfer, MD, Harvard Medical School; Babette Stanton, PhD, Boston University School of Medicine; Peter H. Stone, MD, Harvard Medical School; Patricia Tennis, PhD, University of North Carolina; Thomas J. Thom, National Heart, Lung, and Blood Institute; David Waters, MD, Montreal Heart Institute; Deborah Wingard, PhD, University of California, San Diego.



NOW, CLOSE
THE LOOP...
IN MILD, MODERATE,
AND SEVERE HEART FAILURE
(NYHA Class II, III, and IV)
SQUIBB

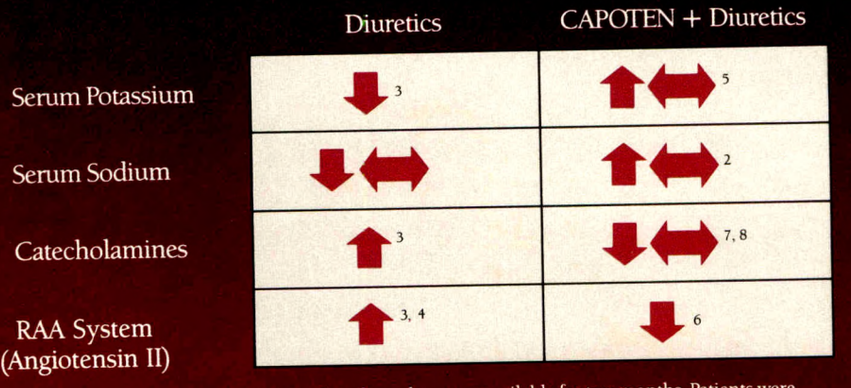
ADD CAPOTEN® SOONER*...
(captopril tablets)

*CAPOTEN is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis. In using CAPOTEN, consideration should be given to the risk of neutropenia/agranulocytosis. Use special precautions in patients with impaired renal function, collagen vascular disorders, or those exposed to other drugs known to affect the white cells or immune response. Evaluation of heart failure patients should always include assessment of renal function. See INDICATIONS AND USAGE, CONTRAINDICATIONS, WARNINGS, and ADVERSE REACTIONS in the brief summary of prescribing information on last page.

COMPLETE THE JOB YOUR LOOP DIURETIC STARTED

In patients symptomatic on diuretic and digitalis

- Adding CAPOTEN enhances the diuretic effect of furosemide
  - —Disappearance of edema in 55% of a subgroup of patients after adding CAPOTEN to furosemide†[1]
  - —50% reduction in furosemide dose‡[2]
- Helps normalize electrolyte and neurohormone levels



†Patients for whom data were available for two months. Patients were NYHA Class II, III, and IV receiving concomitant diuretic and digitalis therapy.

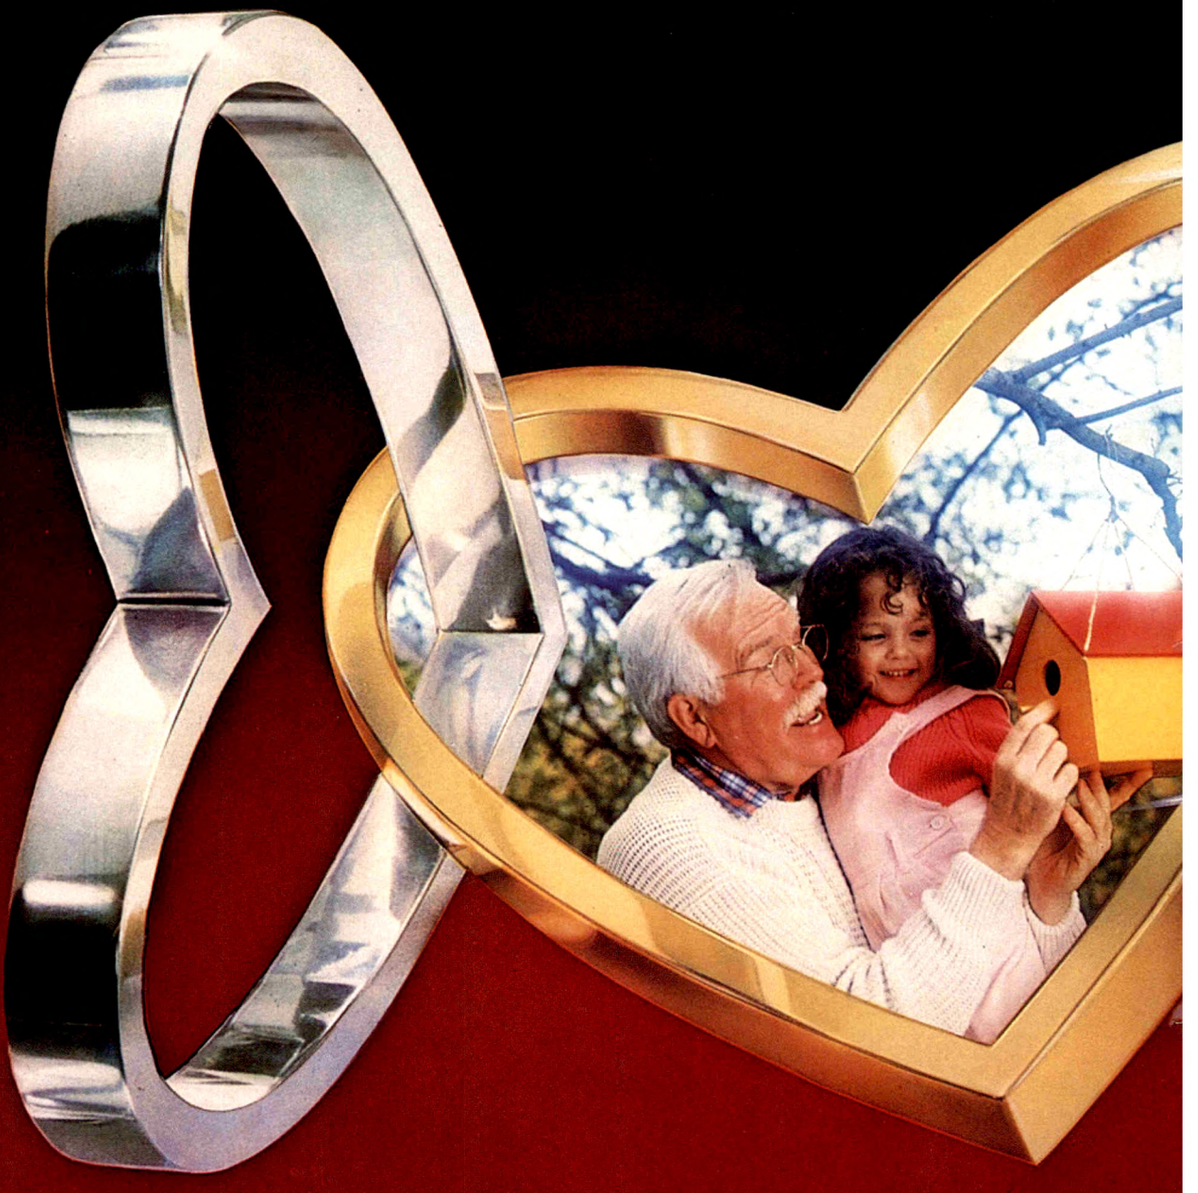
‡Fourteen patients were NYHA Class III and IV receiving concomitant diuretic and digitalis therapy.

IN MILD, MODERATE, AND SEVERE HEART FAILURE
(NYHA Class II, III, and IV)

CAPOTEN®
(captopril tablets)

CLOSING THE LOOP IN HEART FAILURE THERAPY

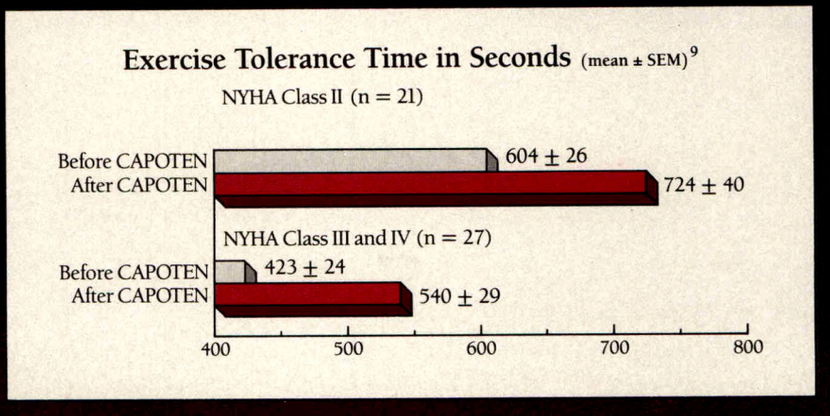
ADD CAPOTEN® SOONER...
(captopril tablets)



818-509

HELPS PATIENTS FEEL AND FUNCTION BETTER

- Adding CAPOTEN improves exercise tolerance times



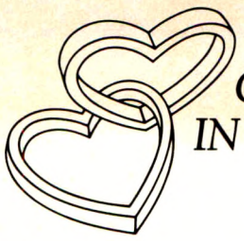
All patients were given diuretics and digitalis throughout the 12-week study period. Adapted from Captopril Multicenter Research Group.[9]

- Improves NYHA Class
  In the same study, patients (n = 49) experienced significant mean improvement in NYHA Class ($P < 0.001$)[9]
  - —Class II Patients (n = 22) improved from 2.5 to 2.1 (± 0.1)
  - —Class III and IV patients (n = 27) improved from 3.0 to 2.4

IN MILD, MODERATE, AND SEVERE HEART FAILURE
(NYHA Class II, III, and IV)

CAPOTEN®
(captopril tablets)

CLOSING THE LOOP IN HEART FAILURE THERAPY



CLOSING THE LOOP IN HEART FAILURE THERAPY

SQUIBB

CAPOTEN® TABLETS

Captopril Tablets

INDICATIONS: Hypertension – CAPOTEN (captopril) is indicated for the treatment of hypertension. Consideration should be given to the risk of neutropenia/agranulocytosis (see WARNINGS). CAPOTEN may be used as initial therapy for patients with normal renal function, in whom the risk is relatively low. In patients with impaired renal function, particularly those with collagen vascular disease, captopril should be reserved for those who have either developed unacceptable side effects on other drugs, or have failed to respond satisfactorily to drug combinations. CAPOTEN is effective alone and in combination with other antihypertensive agents, especially thiazide-type diuretics.

Heart Failure: CAPOTEN (captopril) is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.

CONTRAINDICATIONS: CAPOTEN is contraindicated in patients who are hypersensitive to this product.

WARNINGS: Neutropenia/Agranulocytosis – Neutropenia ($< 1000/mm^3$) with myeloid hypoplasia has resulted from use of captopril. About half of the neutropenic patients developed systemic or oral cavity infections or other features of the syndrome of agranulocytosis. The risk of neutropenia is dependent on the clinical status of the patient:

In clinical trials in patients with hypertension who have normal renal function (serum creatinine less than 1.6 mg/dL and no collagen vascular disease), neutropenia has been seen in one patient out of over 8,600 exposed. In patients with some degree of renal failure (serum creatinine at least 1.6 mg/dL) but no collagen vascular disease, the risk in clinical trials was about 1 per 500. Doses were relatively high in these patients, particularly in view of their diminished renal function. In patients with collagen vascular diseases (e.g., systemic lupus erythematosus, scleroderma) and impaired renal function, neutropenia occurred in 3.7% of patients in clinical trials. While none of the over 750 patients in formal clinical trials of heart failure developed neutropenia, it has occurred during the subsequent clinical experience. Of reported cases, about half had serum creatinine ≥ 1.6 mg/dL and more than 75% received procainamide. In heart failure, it appears that the same risk factors for neutropenia are present.

Neutropenia has appeared usually within 3 months after starting therapy, associated with myeloid hypoplasia and frequently accompanied by erythroid hypoplasia and decreased numbers of megakaryocytes (e.g., hypoplastic bone marrow and pancytopenia); anemia and thrombocytopenia were sometimes seen. Neutrophils generally returned to normal in about 2 weeks after captopril was discontinued, and serious infections were limited to clinically complex patients. About 13% of the cases of neutropenia have ended fatally, but almost all fatalities were in patients with serious illness, having collagen vascular disease, renal failure, heart failure or immunosuppressant therapy, or a combination of these complicating factors. **Evaluation of the hypertensive or heart failure patient should always include assessment of renal function.** If captopril is used in patients with impaired renal function, white blood cell and differential counts should be evaluated prior to starting treatment and at approximately 2-week intervals for about 3 months, then periodically. In patients with collagen vascular disease or who are exposed to other drugs known to affect the white cells or immune response, particularly when there is impaired renal function, captopril should be used only after an assessment of benefit and risk, and then with caution. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat, fever). If infection is suspected, perform white cell counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count $< 1000/mm^3$) withdraw captopril and closely follow the patient's course.

Proteinuria: Total urinary proteins >1 g per day were seen in about 0.7% of patients on captopril. About 90% of affected patients had evidence of prior renal disease or received high doses (>150 mg/day), or both. The nephrotic syndrome occurred in about one-fifth of proteinuric patients. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued. The BUN and creatinine were seldom altered in proteinuric patients. Since most cases of proteinuria occurred by the 8th month of therapy with captopril, patients with prior renal disease or those receiving captopril at doses >150 mg per day, should have urinary protein estimates (dip-stick on 1st morning urine) before therapy, and periodically thereafter.

Hypotension: Excessive hypotension was rarely seen in hypertensive patients but is a possibility in severely salt/volume-depleted persons such as those treated vigorously with diuretics (see PRECAUTIONS [Drug Interactions]). In heart failure, where the blood pressure was either normal or low, transient decreases in mean blood pressure >20% were recorded in about half of the patients. This transient hypotension may occur after any of the first several doses and is usually well tolerated, although rarely it has been associated with arrhythmia or conduction defects. A starting dose of 6.25 or 12.5 mg tid may minimize the hypotensive effect. Patients should be followed closely for the first 2 weeks of treatment and whenever the dose of captopril and/or diuretic is increased.

BECAUSE OF THE POTENTIAL FALL IN BLOOD PRESSURE IN THESE PATIENTS, THERAPY SHOULD BE STARTED UNDER VERY CLOSE MEDICAL SUPERVISION.

PRECAUTIONS: General: *Impaired Renal Function* – Hypertension – Some hypertensive patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible. Heart Failure – About 20% of patients develop stable elevations of BUN and serum creatinine >20% above normal or baseline upon long-term treatment. Less than 5% of patients, generally with severe preexisting renal disease, required discontinuation due to progressively increasing creatinine. See DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]. *Valvular Stenosis* – A theoretical concern, for risk of decreased coronary perfusion, has been noted regarding vasodilator treatment in patients with aortic stenosis due to decreased afterload reduction. *Surgery/Anesthesia* – If hypotension occurs during surgery or anesthesia, and is considered due to the effects of captopril, it is correctable by volume expansion.

Drug Interactions: *Hypotension – Patients on Diuretic Therapy* – Precipitous reduction of blood pressure may occasionally occur within the 1st hour after administration of the initial of captopril dose in patients on diuretics, especially those recently placed on diuretics, and those on severe dietary salt restriction or dialysis. This possibility can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy or by initiating therapy with small doses (6.25 or 12.5 mg). Alternatively, provide medical supervision for at least 1 hour after the initial dose.

Agents Having Vasodilator Activity – In heart failure patients, vasodilators should be administered with caution.

Agents Causing Renin Release – Captopril's effect will be augmented by antihypertensive agents that cause renin release.

Agents Affecting Sympathetic Activity – The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

Agents Increasing Serum Potassium – Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium. Use potassium-containing salt substitutes with caution.

Inhibitors of Endogenous Prostaglandin Synthesis – Indomethacin and other nonsteroidal anti-inflammatory agents may reduce the antihypertensive effect of captopril, especially in low renin hypertension.

Drug/Laboratory Test Interaction: Captopril may cause a false-positive urine test for acetone.

Carcinogenesis, Mutagenesis and Impairment of Fertility: Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential. Studies in rats have revealed no impairment of fertility.

Pregnancy: Category C: There are no adequate and well-controlled studies in pregnant women. Embryocidal effects and craniofacial malformations were observed in rabbits. Therefore, captopril should be used during pregnancy, or for patients likely to become pregnant, only if the potential benefit outweighs the potential risk to the fetus. Captopril crosses the human placenta.

Nursing Mothers: Captopril is secreted in human milk. Exercise caution when administering captopril to a nursing woman, and, in general, nursing should be interrupted.

Pediatric Use: Safety and effectiveness in children have not been established although there is limited experience with use of captopril in children from 2 months to 15 years of age. Dosage, on a weight basis, was comparable to that used in adults. CAPOTEN (captopril) should be used in children only if other measures for controlling blood pressure have not been effective.

ADVERSE REACTIONS: Reported incidences are based on clinical trials involving approximately 7000 patients.

Renal – About 1 of 100 patients developed proteinuria (see WARNINGS). Renal insufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patients.

Hematologic – Neutropenia/agranulocytosis has occurred (see WARNINGS). Anemia, thrombocytopenia, and pancytopenia have been reported.

Dermatologic – Rash, (usually maculopapular, rarely urticarial), often with pruritus, and sometimes with fever and eosinophilia, in about 4 to 7 of 100 patients (depending on renal status and dose), usually during the 1st 4 weeks of therapy. Pruritus, without rash, in about 2 of 100 patients. A reversible associated pemphigoid-like lesion, and photosensitivity, have also been reported. Angioedema of the face, mucous membranes of the mouth, or of the extremities in about 1 of 1000 patients – reversible on discontinuance of captopril therapy. One case of laryngeal edema has been reported. Flushing or pallor in 2 to 5 of 1000 patients.

Cardiovascular – Hypotension may occur; see WARNINGS and PRECAUTIONS [Drug Interactions] for discussion of hypotension on initiation of captopril therapy. Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocardial infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 1000 patients.

Dysgeusia – Approximately 2 to 4 (depending on renal status and dose) of 100 patients developed a diminution or loss of taste perception; taste impairment is reversible and usually self-limited even with continued drug use (2 to 3 months). Gastric irritation, abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulcers, peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, cough, alopecia, paresthesias reported in about 0.5 to 2% of patients but did not appear at increased frequency compared to placebo or other treatments used in controlled trials.

Altered Laboratory Findings: Elevations of liver enzymes in a few patients although no causal relationship has been established. Rarely cholestatic jaundice, and hepatocellular injury with or without secondary cholestasis, have been reported. A transient elevation of BUN and serum creatinine may occur, especially in volume-depleted or renovascular hypertension patients. In instances of rapid reduction of longstanding or severely elevated blood pressure, the glomerular filtration rate may decrease transiently, also resulting in transient rises in serum creatinine and BUN. Small increases in serum potassium concentration frequently occur, especially in patients with renal impairment (see PRECAUTIONS).

OVERDOSAGE: Primary concern is correction of hypotension. Volume expansion with an I.V. infusion of normal saline is the treatment of choice for restoration of blood pressure. Captopril may be removed from the general circulation by hemodialysis.

DOSAGE AND ADMINISTRATION: CAPOTEN (captopril) should be taken one hour before meals. In hypertension, CAPOTEN may be dosed bid or tid. Dosage must be individualized; see DOSAGE AND ADMINISTRATION section of package insert for detailed information regarding dosage in hypertension and in heart failure. Because CAPOTEN (captopril) is excreted primarily by the kidneys, dosage adjustments are recommended for patients with impaired renal function.

Consult package insert before prescribing CAPOTEN (captopril).

HOW SUPPLIED: Available in tablets of 12.5, 25, 50, and 100 mg in bottles of 100 (25 mg and 50 mg also available in bottles of 1000), and in UNIMATIC® unit-dose packs of 100 tablets. (J3-658J)

Primary Coronary Artery Dissection Observed at Coronary Angiography

HIDEO NISHIKAWA, MD
SHIGEMOTO NAKANISHI, MD
SHINICHIRO NISHIYAMA, MD
SHIGEYUKI NISHIMURA, MD
AKIRA SEKI, MD
HIROSHI YAMAGUCHI, MD

Primary coronary artery dissection has rarely been reported since Pretty's first description in 1931.[1] Earlier cases, which were diagnosed incidentally at autopsy, yielded a clinical picture of catastrophic acute coronary artery disease, revealed either by sudden death (62%) or acute myocardial ischemia (38%).[2] Recently, however, the diagnosis has been made on clinical grounds. Among the 15 previous case reports of primary coronary artery dissection documented by coronary arteriogram (Table I), the diagnosis was made during coronary angiogram conducted for initial examination of acute myocardial infarction in 13 and during coronary angiogram performed under a diagnosis of angina pectoris in 2 patients.

We discovered 4 patients (0.28%) with primary coronary artery dissection among 1,445 consecutive patients with an angiographically final diagnosis of myocardial infarction (Table II). Primary coronary artery dissection may thus be more common than believed. Further, Shin et al[3] reported 2 cases of primary coronary artery dissection among 45 consecutive autopsied patients with cardiac diseases in the Sakurabashi Watanabe Hospital, Osaka. These results suggests that this entity may be more frequent in Japan.

Coronary angiograms of our 4 patients (Figures 1 to 5) revealed features common to all previous dissections: (1) a thin radiolucent line, that is, flap, indicating partial separation of the intima/media; (2) filling of the dissection sac; and (3) irregularity in caliber with widened or narrowed segments.[2] Reversibility of these changes is possible, and in follow-up studies, was particularly evident in dissections when reentry occurred spontaneously.[4] In case 2, we observed an angiographic return to relative patency of the segment of the right coronary artery, with partial resolution of the dissection (Figure 3), possibly reflecting thrombosis, retraction and dissolution of the dissection's hematoma in a manner similar to that demonstrated angiographically with aortic dissections.

Various hypotheses have been advanced to explain the etiology of primary coronary artery dissection. Preexisting coronary arteritis has frequently been described.[5] However, this change may simply be a response to the intramural hematoma rather than an underlying condition.[6] Histologic cystic medial necrosis has been reported more often, and Boschetti et al[7] took this as evidence of a preexisting brittleness of the media. Morise et al,[8] however, noted the same histologic features in 3 cases of iatrogenic coronary artery dissection. Bonnet et al[9] observed impaired collagen synthesis in an in vitro study of skin fibroblasts in a postpartum woman with primary coronary artery dissection. Low collagen synthesis may be responsible for an alteration in the mechanical function of vessel walls, leading to primary coronary artery dissection. The fre-

4	28, F	Anteroseptal	0	1	LAD	Medical	Died (4 yrs)

LAD = left anterior descending; + = positive; 0 = negative.

quency with which these dissections develop in young women, particularly during peripartum, as seen in case 4, may lend support to the role of hormones, because the association of pregnancy and aortic dissection is well known.[2] The report by Mark et al[10] of a patient with variant angina and angiographic evidence of primary coronary artery dissection is the only one of an association between variant angina and primary coronary artery dissection. However, we observed preexisting angina at rest, suggestive of variant angina, in cases 1 and 2. These 2 patients had no exertional chest pain. We assume that coronary vasospasm may have been the primary event. Variant angina has been described to occur more often in Japan, and may contribute to the prevalence of primary coronary artery dissection.

The treatment for primary coronary artery dissection has not been established because this disease was lethal in most previous patients (Table I). Surgical intervention was attempted in 5 patients: an internal mammary artery implant in 1, bypass and aneurysmectomy of the left ventricle in 1 and isolated bypass in 3. In the 11 remaining patients, including our 4, only medical treatment was attempted.

Effect of Right Coronary Artery Occlusion During Percutaneous Transluminal Coronary Angioplasty on Right Ventricular Performance

MANFRED MAUSER, MD
KARL R. KARSCH, MD
LUDGER SEIPEL, MD

The effects of acute ischemia on left ventricular volumes and function have been studied extensively in animal models and, more recently, in patients with coronary artery disease during percutaneous transluminal coronary angioplasty (PTCA) of the left coronary artery.[1,2] Less attention, however, has been focused on the performance of the right ventricle in patients with chronic coronary artery disease or during acute occlusion of the right coronary artery (RCA). In patients with coronary artery disease, ischemia induced by balloon inflation during PTCA is a setting comparable to short-term coronary artery occlusion in the animal laboratory, and provides the opportunity to study the effects of acute ischemia on ventricular function in humans.

We describe the effects of acute ischemia on right ventricular (RV) performance in patients undergoing PTCA of the RCA.

Ten symptomatic patients with 1-vessel disease of the RCA without a history or electrocardiographic signs of a previous transmural myocardial infarction were studied. There were 7 men and 3 women with a mean age of 58 years (range 47 to 70). In each patient a single stenosis of at least 70% diameter reduction of the proximal RCA suitable for PTCA was documented by coronary angiography performed 1 or 2 weeks before investigation. All patients had a right dominant coronary artery circulation. The stenosis was either proximal (6 patients) or immediate distal (4) to the origin of the first RV branch, such that all ventricular branches were either distal to the balloon or occluded by the inflated balloon. The distal RCA was always filled anterograde and not by visible collaterals from the left coronary artery. The ventriculogram of the left ventricle showed a normal left ventricular wall motion in 9 patients and a severe hypokinetic diaphragmatic wall segment in 1 patient. All patients were receiving long-term therapy with calcium antagonists and long-acting nitrates. Two patients had additional β-blocker medication. No patient had significant valvular heart disease, evidence of pulmonary disease or unstable angina pectoris.

A 7Fr Swan-Ganz balloon-tipped catheter was advanced into the pulmonary artery via the left femoral vein. From the right femoral vein, a 7Fr pigtail catheter was placed into the right ventricle. Correct placement of the catheter was controlled by pressure recording. After basal pressure measurements a control ventriculogram with 10 ml of contrast material was obtained and the catheter position was corrected for a good opacification of the right ventricle without causing premature ventricular beats during injection. For pressure measurements fluid-filled Statham pressure transducers were used. For the biplane ventriculogram of the RV (30° right anterior oblique, 60° left anterior oblique) 40 ml of a nonionic contrast material (Ultravist 360, Schering Berlin) was injected into the RV with a flow of 10 ml/s and documented with a film speed of 50 frames/s. Standard PTCA equipment with a 9Fr arterial sheet within the right femoral artery was used. Balloon size of the dilatation catheter was selected according to the vessel diameter. A total of 3 to 5 occlusions were performed in each patient. The duration of each balloon inflation was 60 seconds. During the inflation period RV pressures, pulmonary artery pressure and heart rate were recorded. A second ventriculogram of the RV was performed at the end of the first occlusion period after at least 45 seconds of balloon inflation. The time interval between the 2 ventriculograms was at least 20 minutes. As noted by others, contrast medium has no persistent effect on hemodynamics within that time period. Care was taken to maintain the patients position unchanged and both ventriculograms were performed during inspiration. All patients gave their informed consent and there were no complications directly related to the research procedure.

The volumes of the right ventricle were analyzed according to the method described by Arcilla et al.[3] The regression equation was $y = 0.762x + 2.81$ *(x is the uncorrected and y the corrected volume). End-diastolic volume index, end-systolic volume index, stroke*

EDVI = end-diastolic volume index; ESVI = end-systolic volume index; EF = ejection fraction; HR = heart rate; PAP = pulmonary artery pressure; RVEDP = right ventricular end-diastolic pressure; SVI = stroke volume index.
* $p < 0.05$; † $p < 0.001$.

volume index and ejection fraction were calculated. Because ventricular volumes are influenced by the injected contrast material after 3 to 5 beats,[4] only the second or third beat after the onset of the injection was analyzed. Patients with premature ventricular contractions during the first beats were excluded from the study. Results are given as mean ± standard deviation. For statistical analysis Student paired t test was used.

Heart rate and the afterload of the right ventricle (pulmonary artery pressure) were not significantly influenced by the 60 second occlusion of the RCA (Table I). Right ventricular end-diastolic pressure increased significantly from 3.7 ± 1.2 to 8.3 ± 1.8 mm Hg ($p < 0.001$) and reached the elevated level after 24 ± 7 seconds. Together with the RV diastolic pressure the RV volumes increased markedly: end-diastolic volume index +25.5% ($p < 0.001$) and end-systolic volume index +72.2% ($p < 0.001$) (Table I). A significant decrease of the RV ejection fraction from 52 ± 3 to 33 ± 8% ($p < 0.001$) was found at the end of the balloon inflation period (Table I).

Several experimental studies have evaluated the effect of RCA occlusion on the RV hemodynamics. Brooks et al[5] demonstrated in a dog model that complete occlusion of the RCA at normal pulmonary artery pressures caused a decrease in RV contractile force without a change in RV filling pressure. In the pig,[6] whose coronary anatomy is more closely comparable to humans, total occlusion of the RCA produced a decrease of RV contractile force but also led to an increase of RV end-diastolic pressure. The described changes of RV function during ischemia were more pronounced if the pulmonary artery pressure was increased above normal values.[5]

In humans, Berger et al[7] studied the RV response to exercise in patients with coronary artery disease in a radionuclide ventriculography study. They described an abnormal exercise reserve of the right ventricle in these patients. RV dysfunction was independent of the presence or absence of a proximal RCA stenosis. Therefore they concluded that RV dysfunction during exercise is most likely due to an interaction between the left and right ventricle and not a consequence of RV ischemia due to a limited blood supply by the diseased RCA. In this study, however, no objective parameters of a RV ischemia were assessed, and ischemic dysfunction cannot easily be separated from ventricular interactions by morphologic parameters.

Ferlinz et al[8] described subnormal values of RV volumes (end-diastolic volume index = 61 ml/m²; stroke volume index = 33 ml/m² and ejection fraction = 52%) together with a normal end-diastolic pressure in patients with high-grade lesions of the RCA compared with patients with normal coronary arteries. Because pulmonary artery pressure and RV end-diastolic pressure were normal, these findings cannot easily be related to ischemia with decreased RV compliance or to RV afterload. Ferlinz et al[8] concluded that a reduced Frank-Starling effect may play a role in these patients.

The results of the present study—a reduced RV volume and ejection fraction together with normal RV filling pressures in patients with a significant stenosis of the RCA—are in good accordance with the findings of Ferlinz et al.[8] Acute short-term occlusion of the

RCA during PTCA results in a dramatic decrease of RV global function and a 38% decrease of RV ejection fraction. This is comparable to the response of the left ventricle to ischemia chamber volumes and end-diastolic pressure increases, which show a low tolerance of the human right ventricle even to short periods of ischemia. Therefore, in patients with an acute proximal occlusion of the RCA the clinical course may be influenced by the occurrence of RV failure.

Recovery of Severe Ischemic Ventricular Dysfunction After Coronary Artery Bypass Grafting

DAVID A. BRILL, MD
LAWRENCE I. DECKELBAUM, MD
MICHAEL S. REMETZ, MD
ROBERT SOUFER, MD
JOHN A. ELEFTERIADES, MD
BARRY L. ZARET, MD

Ventricular wall motion abnormalities at rest are believed to be indicative of myocardial scar and fibrous tissue. Although patients may have reversible wall motion abnormalities at rest during periods of ischemia, recent evidence suggests that reversible ventricular dysfunction can persist after a major ischemic insult.[1,2] Braunwald and Rutherford[3] distinguish between stunned and hibernating myocardium and suggest that in either situation, revascularization can reverse exercise-induced ischemic dysfunction.[4,5] However, reversal of prolonged resting ventricular dysfunction is not as clear. We report a patient with severe coronary artery disease without myocardial infarction who had complete reversal of marked left ventricular (LV) dysfunction.

A 40-year-old man was healthy, physically active and free of any symptoms of cardiac dysfunction until 2 weeks before admission when he developed exertional dyspnea and angina pectoris. His symptoms increased, leading to hospitalization. He had had a pulmonary embolus at age 25 after knee surgery. His only medications were chlorpromazine 500 mg daily and temazepam 60 mg daily for post-traumatic stress disorder. He smoked a pack of cigarettes a day and had a

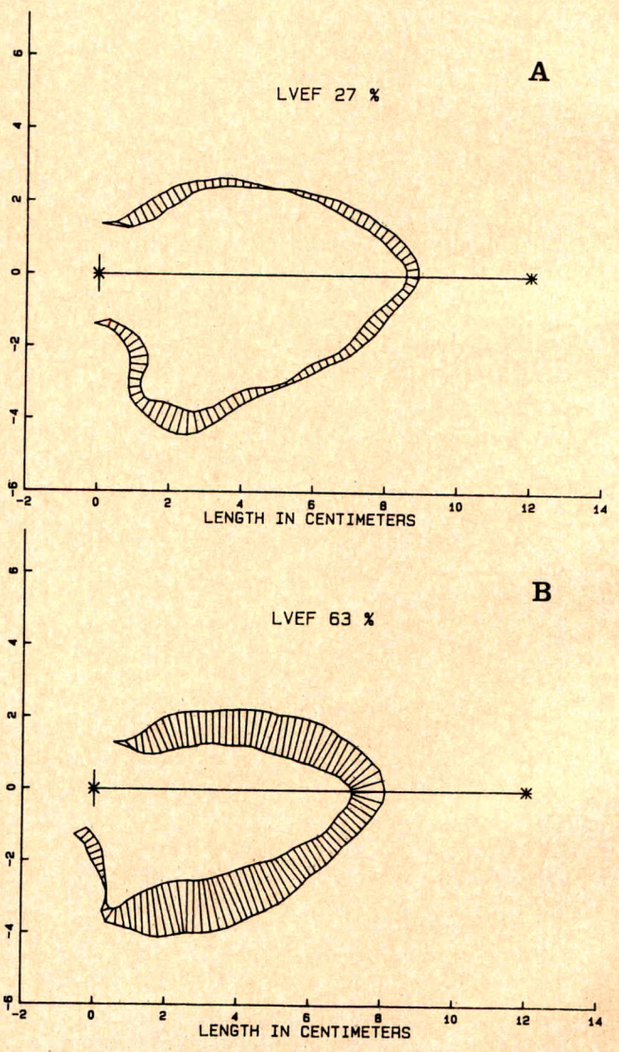

FIGURE 1. Left ventriculography before and after coronary artery bypass grafting. Diastolic and systolic ventricular outlines from right anterior oblique angiocardiograms are shown from the initial (*A*) and follow-up (*B*) catheterizations. Regional wall motion is represented by the chords that plot the excursion of each perimeter segment. Improved regional contraction involving all segments resulted in a global ejection fraction increase from 27% preoperatively to 63% 2 months postoperatively.

paternal family history of ischemic cardiac disease. He had bibasilar rales, a fourth heart sound and a soft systolic ejection murmur. The electrocardiogram revealed sinus rhythm at a rate of 95/min with biphasic T waves in leads I, aVL and V_4 through V_6. His chest x-ray was normal. He was admitted to the coronary care unit and was treated with lidocaine and nitroglycerin ointment. Serum creatine kinase levels remained within normal limits and his electrocardiogram did not change from admission. He had no further angina.

Cardiac catheterization on the third hospital day revealed globally depressed LV function with an ejection fraction of 27% (Figure 1A). He had a 90% diameter stenosis of the left main coronary artery. The right coronary, left circumflex and left anterior descending arteries had insignificant narrowings. An equilibrium radionuclide angiocardiogram on the same day revealed an LV ejection fraction of 17% with severe generalized hypokinesis. On the fourth hospital day he underwent coronary artery bypass grafting (CABG) with a left internal mammary graft to the left anterior descending artery and a saphenous vein graft to the left circumflex artery. At surgery, inspection of his heart revealed no evidence of acute myocardial infarction. He recovered uneventfully. A repeat equilibrium radionuclide angiocardiogram on the tenth hospital day revealed an LV ejection fraction of 36% without discrete regional wall motion abnormalities. The results of exercise tolerance test performed 5 weeks postoperatively were normal. An equilibrium radionuclide angiocardiogram performed 6 weeks postoperatively revealed an LV ejection fraction of 52%. The patient was readmitted to the hospital 8 weeks postoperatively with atypical chest pain and no electrocardiographic changes. Cardiac catheterization at that time revealed patent grafts and an LV ejection fraction of 63% (Figure 1B).

This report documents total reversal of severe global LV dysfunction as a result of CABG. Reversal of regional wall motion abnormalities at rest[4] and improvement in exercise LV ejection fraction[5] have been reported after CABG. However, the initial ejection fractions in these reports were normal or minimally abnormal and improved only modestly. Akins et al[6] reported 2 patients with previous history of myocardial infarction and severely depressed LV ejection fraction but without evidence of acute ischemia. Both patients had improvement in ejection fraction after revascularization (15 to 27% in 1 patient and 15 to 33% in the other). No previous report has documented complete reversal of severe LV dysfunction at rest following CABG. The improvement in ejection fraction over 6 weeks from 17 to 52% (an increase of 206%) in our patient is a dramatic example of the potential for reversible ischemic dysfunction.

The pathophysiology of persistent myocardial dysfunction in ischemic heart disease is not well understood. Matsuzaki et al[2] demonstrated in a dog model that prolonged partial occlusion of coronary arteries (5 hours) resulted in sustained myocardial dysfunction lasting several days before recovery. Braunwald and Kloner[1] in their review of stunned myocardium concluded that similar effects could be produced by repetitive ischemic episodes or brief total occlusion of the circulation. Ventricular dysfunction in our patient was most likely the result of either stunned myocardium secondary to an ischemic event, ongoing silent ischemia (hibernating myocardium) or both. The patient's repeated episodes of angina may have induced prolonged depression of systolic LV function. The recovery of LV dysfunction following CABG suggests that the myocardium was chronically ischemic and hibernating, not necrotic. The serial improvement in ejection fraction suggests myocardial stunning with the gradual return of function of postischemic reperfused myocardium.

Allorhythmic Preexcitation due to Anterograde Concealed Kent Bundle Conduction

GAETANO SATULLO, MD
GIUSEPPE ORETO, MD
FRANCESCO LUZZA, MD
GIUSEPPE PALEOLOGO, MD
LEO SCHAMROTH, MD

Intermittent preexcitation is due to intermittent block of the impulse within the accessory pathway.[1] When such intermittency occurs, the preexcitation complexes usually appear in an irregular distribution pattern. We report an unusual, hitherto undescribed, distribution pattern that can be explained on the basis of concealed trigeminal preexcitation.

The electrocardiogram (Figure 1), part of a 6-minute continuous recording, was recorded from a 34-year-old woman with the Wolff-Parkinson-White syndrome. The tracing reflects intermittent preexcitation. There are QRS complexes that are narrow and associated with a normal PR interval, and others that have a delta wave and a short PR interval. The distribution of the preexcitation complexes, however, is not haphazard but conforms with an unusual but distinct pattern. Thus, the normal complexes that intervene between 2 successive preexcitation beats are almost always in numbers of 2, 5 or 8 (Figure 1, Table I). In a further section of the recording, however, a few exceptions did occur where the intervening normal beats were in numbers of 1, 4 or 10 (Figure 2, Table I). These exceptions were always associated with a distinct shortening of the first sinus cycle after an impulse conducted through the accessory pathway.

From the Istituto Pluridisciplinare di Clinica Medica, Cattedra di Malattie Cardiovascolari, Universitá di Messina, Italy, and the Department of Medicine, Baragwanath Hospital, and the University of the Witwatersrand, Johannesburg, South Africa. Manuscript received March 3, 1986; revised manuscript received and accepted November 12, 1987.

TABLE I Analysis of the Number of Normal Beats Intervening Between Two Consecutive Preexcitation Beats

Number of normal intervening beats	0	1	2	3	4	5	6	7	8	9	10
Frequency	0	5	55	0	1	9	0	0	10	0	2

In the case presented here, the preexcitation beats occur according to a pattern that could be defined as a trigeminal or a concealed trigeminal distribution. Schamroth and Marriott[2] noted that in the presence of a seemingly haphazard distribution of ventricular extrasystoles, the manifestation of intervening sinus beats in numbers that conform to the formula of $3n - 1$ (2, 5, 8, 11 and so forth) reveals a regular ectopic discharge; the ectopic focus discharges after every 2 sinus impulses. Some of the ectopic depolarizations, however, are not manifest because they are confined to the ectopic focus. On an analogous basis, the occurrence of preexcitation beats that are separated by normal beats in numbers of 2, 5 or 8 (apart from the exceptions to be discussed separately) suggests the presence of a regular 3:1 block within the accessory pathway. The distribution pattern of the intervening normal beats that

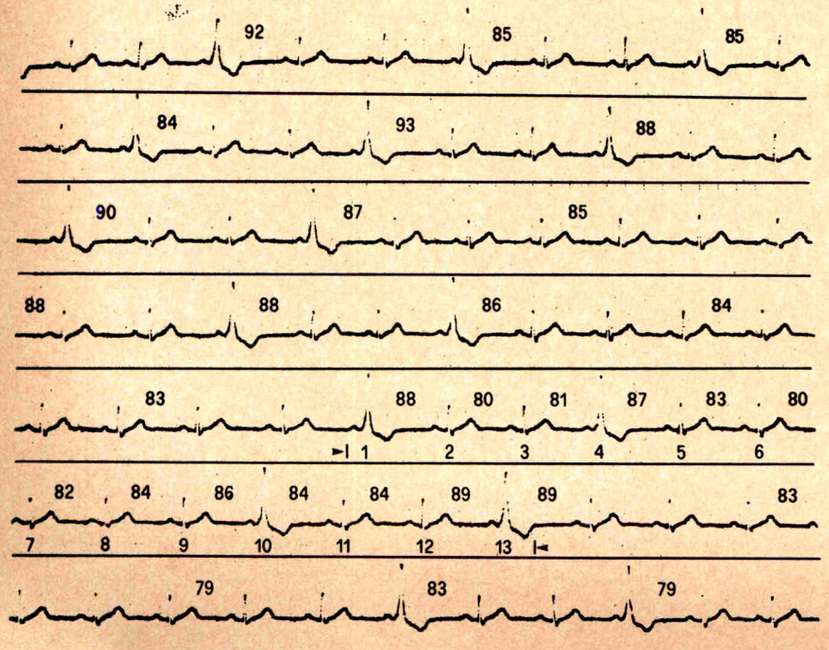

FIGURE 1. Electrocardiogram: continuous recording of standard lead I. The section between the arrows is diagrammed in Figure 3. Numbers above the tracing express the PP intervals in hundredths of a second. Numbers below the tracing label the beats that are diagramatically represented in Figure 3.

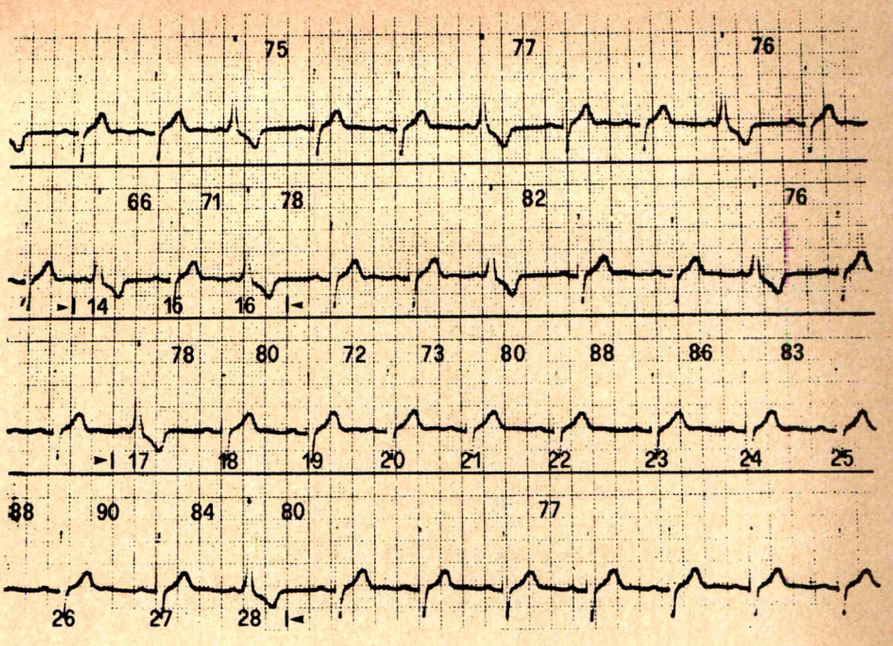

FIGURE 2. Electrocardiogram: continuous recording of lead V_6. Symbols as in Figure 1.

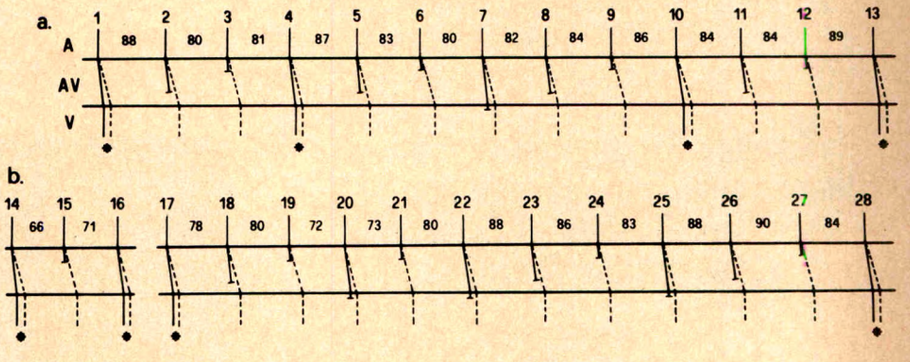

FIGURE 3. Ladder diagram illustrating atrioventricular conduction of sinus impulses. Conduction through the atrioventricular node and the His bundle is reflected by the *dashed lines*. *Solid lines* represent conduction through a Kent bundle. The sinus impulses are labeled with progressive numbers. The preexcitation complexes are labeled with asterisks. PP intervals are expressed in hundredths of a second. *A* and *B* refer to Figures 1 and 2, respectively. See text.

conform to the formula of $3n - 1$ suggests that 3:1 block regularly occurs in the accessory pathway, with some of the impulses penetrating the accessory bundle, but not reaching the ventricles.

The analysis of this phenomenon is shown in Figure 3A. All the sinus impulses are regularly conducted by the normal atrioventricular pathway, as reflected by the dashed lines; conduction through the Kent bundle is represented by the solid lines. The term "conduction" will hereafter only be applied to anterograde conduction of the impulse through the accessory pathway. Impulse 1 is conducted, resulting in a preexcitation complex. Impulses 2 and 3 are blocked. Impulse 2, however, penetrates deeply into the accessory pathway, undergoing a distal block, while impulse 3 is blocked in a proximal zone of the accessory pathway. The deep penetration of impulse 2 is thus responsible for the block of impulse 3. The proximal block of impulse 3 enables impulse 4 to be conducted as would occur after the block of a classic Wenckebach sequence. Thereafter, impulse 4 is conducted in a similar manner to impulse 1; and impulses 5 and 6 are conducted like impulses 2 and 3. The first 4 beats of the diagram thus represent 3:1 Kent bundle conduction. If this pattern is continuous, impulse 7 would be expected to be conducted. It does not do so, however, and the next preexcitation beat is associated with impulse 10. Thus, the 2 preexcitation beats associated with impulses 4 and 10 are separated by 5 intervening normal beats. And if impulse 10 did not result in preexcitation, the next preexcitation beat would be associated with impulse 13, so that 8 intervening normal beats would manifest. Thus, impulses number 1, 4, 7, 10 and so forth are actually conducted through the accessory pathway. Some of them, however, do not result in preexcitation, probably due to block at ventricular level as a consequence of a "mismatch impedance." In other words, the sinus impulse traverses the Kent bundle and reaches the ventricle, but the impulse conducted by the thin accessory pathway constitutes too weak an electrical signal for it to be propagated to the relatively large ventricular mass.[3-5] The presence of anterograde

concealed conduction in the accessory pathway is thus suggested by the occurrence of preexcitation beats in trigeminal or concealed trigeminal distribution.

On the other hand, there is no data supporting the presence of retrograde concealed conduction into the Kent bundle, namely the retrograde penetration of the accessory pathway by sinus impulses conducted through the His bundle.

The exceptions to the formula of concealed trigeminal Kent bundle conduction are shown in Figure 3B. These exceptions only occur when the PP interval after a conducted impulse is distinctly short. Thus beat 14—a preexcitation complex—is followed by a PP interval of 0.66 second. As a result, impulse 15 cannot penetrate deeply into the Kent bundle, as occurs after a longer PP interval, but it is blocked in a proximal zone of the accessory pathway. This enables impulse 16 to be conducted through the accessory pathway, giving rise to a preexcitation complex. The lack of penetration of impulse 15 explains the apparent paradoxic improvement of the conduction ratio with an increase in sinus rate, that is, the change from 3:1 to 2:1 accessory pathway conduction.

A further manifestation of this phenomenon is also shown in Figure 3B. This illustrates 10 normal beats that intervene between successive preexcitation complexes. Impulse 17 results in preexcitation, while impulses 18 and 19 are blocked. Impulse 20, which can be potentially conducted by the accessory pathway to the ventricles, is, however, associated with a normal beat. This lack of ventricular preexcitation is due to mismatch impedance. Impulse 21, then, reaches the Kent bundle after a critically short PP interval, and suffers a proximal block. Impulse 22 is thus conducted, but does not result in preexcitation for the same reason associated with impulse 20. The next preexcitation beat is associated with impulse 28. As with the preceding example, the exception to the formula $3n - 1$ is due to the inordinately short PP interval after impulse 20. This exception occurred when a PP interval after a *conducted* beat was <0.74 second. Shorter PP intervals that follow *nonconducted* impulses do not affect the regular trigeminal or concealed trigeminal pattern of the preexcitation.

Permanent epicardial pacemaker therapy is occasionally required in newborn infants for congenital complete heart block and in young infants for surgically acquired heart block.[1,2] In addition to the usual concerns encountered in any age group, such as lead fracture, pacemaker dysfunction, pericardial effusion and infection,[3-5] infants present the additional problem of requiring an adequate length of wire to allow for growth. We report an unusual complication of pacemaker therapy in a newborn: cardiac strangulation.

From the Departments of Pediatrics, Radiology and Surgery, the University of Maryland School of Medicine—UMH, 22 South Greene Street, Baltimore Maryland. Manuscript received October 30, 1987; revised manuscript received and accepted November 13, 1987.

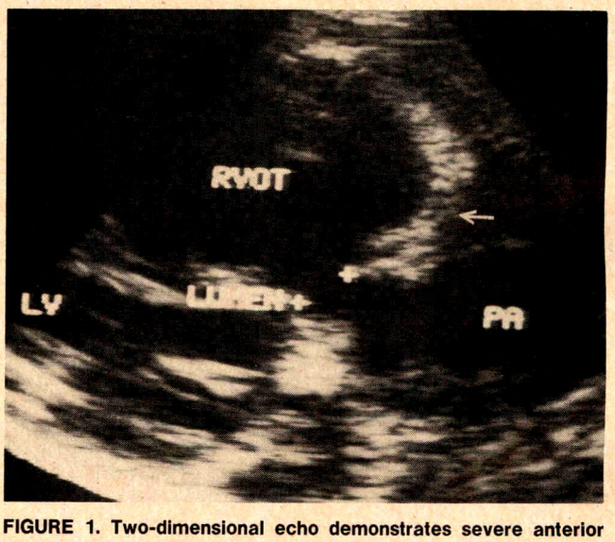

FIGURE 1. Two-dimensional echo demonstrates severe anterior compression of the right ventricular outflow (RVOT) by the pacemaker wire (*arrow*), with only the posterior lumen providing connection to the pulmonary artery (PA). Massive enlargement of the RVOT and compression of the left ventricle (LV) is also noted.

A.B. initially presented 8 weeks before delivery for evaluation of fetal bradycardia, caused by complete atrioventricular block. The atrial rate was 140 beats/min, while the ventricular rate varied between 40 and 50 beats/min. A structurally normal heart with biventricular dilatation was noted in utero. No pleural or pericardial effusion was demonstrated. The pregnan-

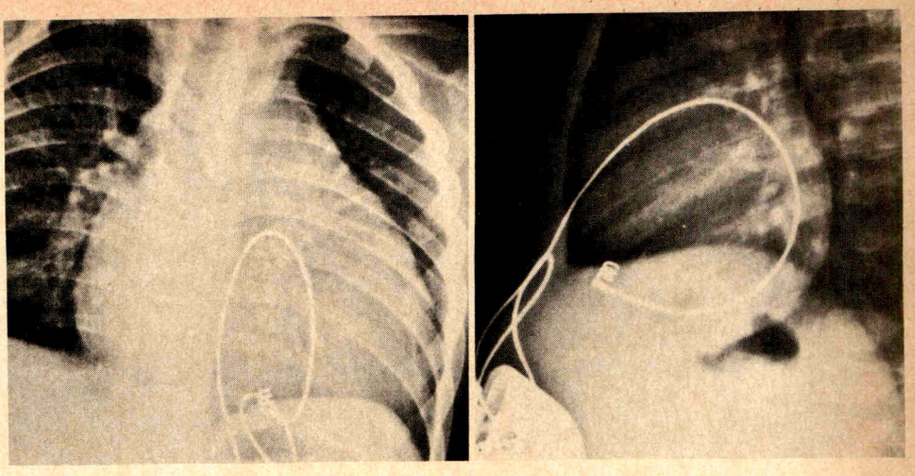

FIGURE 2. Anterior-posterior and lateral chest x-ray showing pacemaker wire encircling the heart.

cy terminated at 36 weeks by spontaneous delivery of a 2.8 kg infant with ventricular rates in the 40 beats/min range and clinical evidence of congestive heart failure and poor perfusion. Temporary endocardial pacemaker therapy was performed and the baby stabilized. At 6 days of age a permanent epicardial pacemaker was placed in a subcutaneous pocket in the left upper quadrant of the abdomen and a permanent screw-in epicardial electrode was inserted onto the diaphragmatic surface of the right ventricle. A loop of pacemaker wire was left in the anterior pericardium as well as in the abdominal cavity. Symptoms of congestive heart failure resolved after permanent pacing, and normal growth and development ensued. Cardiac evaluations during 15 months of follow-up were unremarkable except for paced ventricular rhythm, which gradually decreased to 69 beats/min.

At 20 months of age the child was brought to the emergency room with a 3-day history of frequent falling, intermittent pain in the right arm and syncope. At the time of examination he was in no distress. The heart rate was 69 beats/min, and an electrocardiogram demonstrated a paced ventricular rhythm. Cardiac examination was pertinent for a grade III/VI, harsh ejection systolic murmur along the left sternal edge. The liver was palpable 6 cm below the right costal margin, but the peripheral pulses and perfusion appeared normal.

Echocardiography demonstrated a structurally normal heart, with the new finding of massive right atrial and ventricular dilatation. Severe compression of the anterior right ventricular outflow tract (Figure 1) and the posterior left ventricular free wall was noted. Doppler interrogation of the pulmonary artery indicated a peak pressure difference across the right ventricular outflow tract of 80 to 100 mm Hg; color flow study demonstrated a 6-mm posterior lumen in the right ventricle-pulmonary artery connection. Chest x-ray showed the pacing wire encircling the heart (Figure 2). Emergency surgery performed that day confirmed the strangulation of the heart. The pacemaker wire had carved a deep trough in the atrioventricular groove that compressed the right coronary artery, main pulmonary artery (Figure 3), left main coronary artery and left atrium, and encircled the posterior LV wall. The pacing wire was dissected out of its fibrous sheath, brought around the heart and placed below the diaphragm. The patient was discharged the second postoperative week.

Symptoms of dizziness or syncope in a pacemaker-dependent patient should lead to immediate investigation of pacemaker function. In this patient, a dramatic change on physical examination, with evidence of right ventricular hypertension and systemic venous congestion, required additional explanation. Two-dimensional echocardiography and Doppler facilitated the definitive diagnosis of cardiac strangulation by

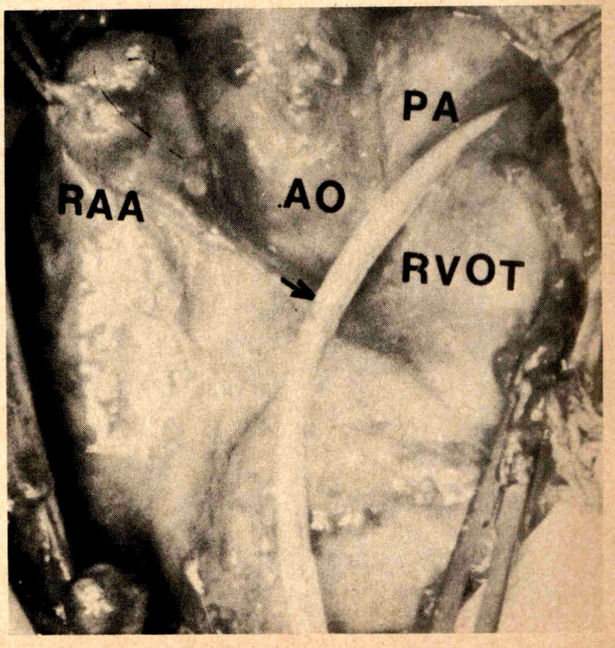

FIGURE 3. Intraoperative photo, confirming compression of right ventricular outflow (RVOT) by pacemaker wire (*arrow*) creating a deep groove as it courses posteriorly. AO = ascending aorta; PA = pulmonary artery; RAA = right atrial appendage.

an epicardial pacemaker electrode. The intermittent complaints of arm pain were likely related to myocardial ischemia from coronary arterial compression, confirmed at the time of surgery. Although the loop of pacemaker electrode was left in the anterior pericardial space, traction, cardiac motion and patient growth resulted in cardiac entrapment with potentially disastrous results.

Incessant Pacemaker Vario® Operation

THOMAS M. CUNNINGHAM, MD

The Vario® function is a feature of certain pacemakers that allows noninvasive voltage threshold determinations.[1] After programming the Vario option, magnet application over the pulse generator results in 16 asynchronous impulses at a frequency of 99/min (new unit), followed by 15 asynchronous impulses at a frequency of 120/min. A stepwise decrease in amplitude occurs during these latter 15 cycles, followed by a final 0 volt output signal. The decrement in voltage per cycle is determined by the programmed amplitude as well as battery status. In a new unit, at a 5 volt output, the step differential is 0.32 volts. Initiation of the Vario test results from engagement of a reed switch by the test magnet. A case is described where failure of the reed switch to disengage after magnet removal led to continuous Vario cycling.

From Palm Drive Hospital, Sebastopol, California. Manuscript received April 20, 1987; revised manuscript received and accepted November 2, 1987.

A 77-year-old man underwent implantation of a Telectronics 255 bipolar VVI pacemaker for atrial fibrillation with complete heart block. Routine pacemaker follow-up 6 months later included noninvasive threshold testing by the Vario technique. After determining a threshold of 1.8 volts (at 0.25-ms pulse duration), the magnet was removed. Despite magnet withdrawal and attempts to program out of the Vario mode, the cyclic pattern persisted, including asystolic pauses from the first subthreshold output pulse until resumption of magnet test rate pacing at 99/min (Figure 1). Other parameters, such as amplitude and pulse width, were likewise unaffected by attempts at reprogramming. The patient was asymptomatic during the asystolic periods, although facial pallor was evident, followed by facial hyperemia during pacing. Surgery was promptly performed, with replacement of the pulse generator. During surgery, manipulation of the original unit in the pocket resulted in cessation of Vario cycling and return of normal pacemaker functioning. A defective reed switch was discovered at the

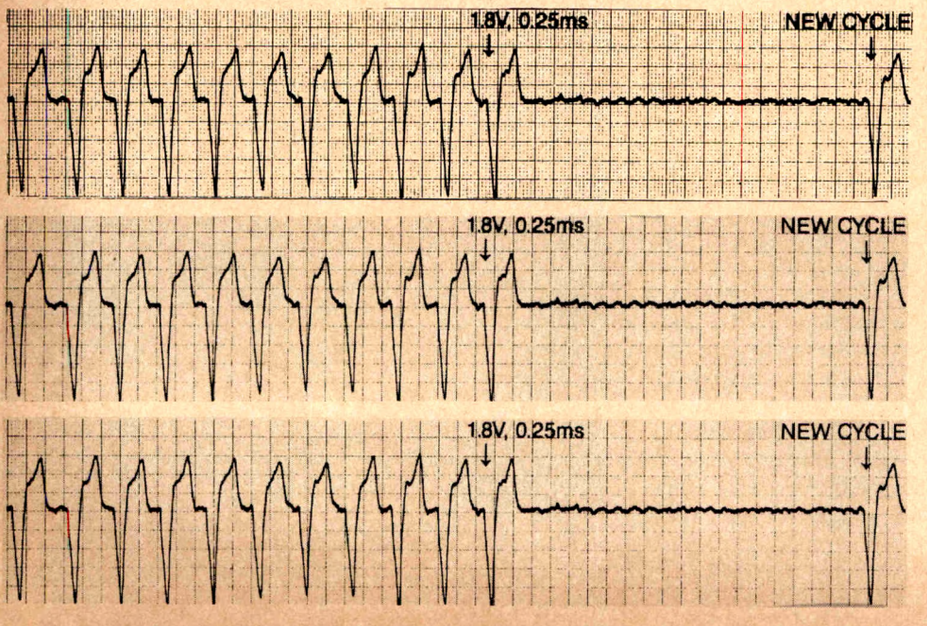

FIGURE 1. Continuous Vario operation, including asystolic pauses, after removal of the test magnet.

time of analysis of the pulse generator (personal communication, Telectronics, Inc.).

Noninvasive threshold determinations are useful in assuring an adequate margin of safety for pacemaker operation, especially when output is reduced to maximize generator longevity. The Vario technique is both easily performed and precise. This report illustrates a possible complication to this method, related to reed switch malfunction, with continuous Vario cycling. In patients in whom pacemaker dependency is present and the threshold is high, dangerously long pauses could result.

Modulation of Atrioventricular Nodal Conduction Using Radiofrequency Current

KLAUS-PETER KUNZE, MD
MICHAEL SCHLÜTER, PhD
MANFRED GEIGER, MD
KARL-HEINZ KUCK, MD

Transvenous catheter ablation of the atrioventricular (AV) node has become a new therapeutic alternative in the treatment of patients with drug-resistant supraventricular tachycardia. After high-energy direct current shocks are delivered to the AV junction, conduction block is achieved in about 80% of patients, with subsequent control of symptoms. Pacemaker implantation, however, is mandatory because no, or only slow, junctional or ventricular escape rhythms emerge after ablation.[1] Therapeutic means currently under investigation for the modification of AV nodal conduction are transcatheter application of radiofrequency current[2] or laser energy.[3] We report the successful modulation of AV nodal conduction by radiofrequency current in a patient with intermittent, medically refractory atrial fibrillation.

A 69-year-old woman was referred to our hospital because of intermittent atrial fibrillation associated with rapid ventricular rates leading to presyncopal attacks. She had been treated unsuccessfully with 7 antiarrhythmic drugs, including amiodarone. The physical examination showed no abnormal findings. Routine laboratory tests, 2-dimensional echocardiogram and chest x-ray all had normal results. The 12-lead electrocardiogram revealed regular sinus rhythm with normal conduction intervals and normal ST segments. Twenty-four hour long-term electrocardiography disclosed that sinus rhythm was frequently interrupted by episodes of atrial fibrillation with ventricular rates of up to 190 beats/min.

After informed written consent had been obtained, the patient underwent an attempt to impair AV nodal conduction by application of radiofrequency current. Standard 6Fr quadripolar USCI electrode catheters were positioned under fluoroscopic control in the high right atrium and the right ventricular apex. An 8Fr bipolar electrode catheter that served for radiofrequency current application was placed at the region of the AV node. A 5Fr arterial cannula allowed continuous measurement of arterial blood pressure. After positioning of the catheters a bolus of 100 U/kg body weight of heparin was given intravenously, followed by infusion of 1,000 U/hour for the next 12 hours. Stimulation was performed with an ERA-S-His stimulator (Biotronik GmbH).

A custom-built radiofrequency generator delivered 300-kHz electrical energy at a constant preset voltage for a variable preset time. The unit allows continuous registration of delivered current and voltage, and, thus, calculation of tissue impedance and delivered power and energy. Six surface electrocardiographic leads, 4 endocardial leads, arterial blood pressure and delivered current and voltage were registered simul-

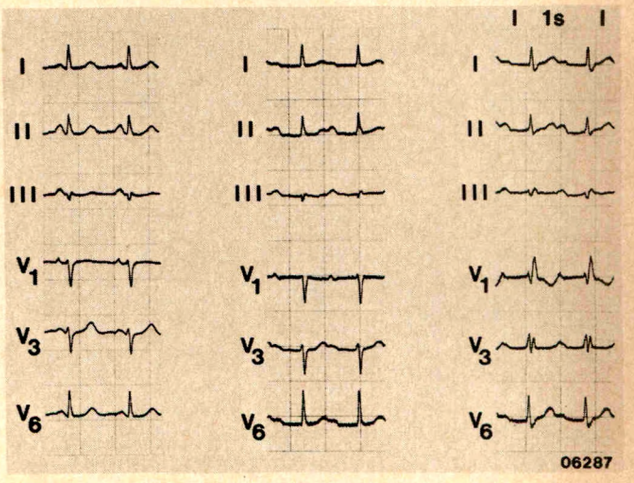

FIGURE 1. Six-lead surface electrocardiograms before radiofrequency application (*left*), after the sixth application (*middle*) and 30 minutes after the last application (*right*). Before radiofrequency application the sinus cycle length was 680 ms and the PQ, QRS and QT intervals were within normal limits. The electrocardiograms after the sixth application and 30 minutes after the last application show a marked prolongation of the PQ interval to 340 ms. Right bundle branch block at the end of the procedure was inadvertently induced by the seventh radiofrequency pulse.

From the Department of Cardiology, University Hospital Eppendorf, Hamburg, Federal Republic of Germany. This work was supported by a grant from the Dr. Werner-Otto-Stiftung, Hamburg, Federal Republic of Germany. Manuscript received August 14, 1987; revised manuscript received November 5, 1987, and accepted November 6.

taneously at a paper speed of 100 mm/s (stimulation study) or 25 mm/s (during radiofrequency application) on a 16-channel recorder (Siemens-Mingograph).

Initially, the anterograde effective refractory period of the AV node and the Wenckebach cycle length were determined (295 ms and 280 ms, respectively). During rapid atrial stimulation for determination of the Wenckebach cycle length, sustained atrial fibrillation with a ventricular rate of 190 beats/min was induced and associated with dizziness and angina. External cardioversion reestablished a stable sinus rhythm, and the ablation procedure was begun. The 8Fr catheter was positioned such that its distal electrode recorded the largest possible atrial potential but also a small His bundle potential. Then a total of 9 radiofrequency pulses of various power and duration were introduced between the catheter tip and a back paddle. After each pulse the AH and PQ intervals and the anterograde AV nodal effective refractory period were determined. With the initial 2 pulses, a power of 13.8 to 14.4 watts was applied for 20 seconds. This did not show a significant effect on AV nodal conduction and refractoriness. With the next 4 pulses, 31 to 34 watts were delivered for 20 seconds, resulting in a marked prolongation of the AH and PQ intervals but only a minor increase of the anterograde AV nodal effective refractory period. We proceeded with 3 pulses of the same power, each lasting 30 seconds. The seventh pulse inadvertently caused right bundle branch block, and the catheter had to be relocated. The subsequent 2 pulses significantly increased the anterograde AV nodal effective refractory period.

After the ninth radiofrequency, third-degree AV nodal block occurred for 22 seconds, but then 1:1 AV nodal conduction resumed. After another 30 minutes the AH interval during sinus rhythm (660 ms cycle length), which had been 60 ms before radiofrequency application, had increased to 240 ms. The PQ interval had increased from 125 to 325 ms and the width of the QRS complex had also increased from 90 to 140 ms, because of the creation of a right bundle branch block.

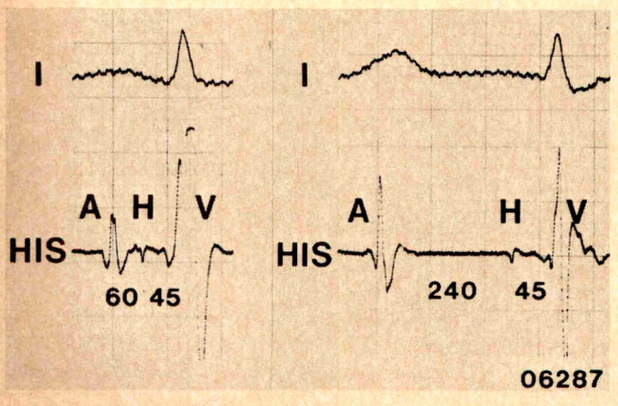

FIGURE 2. Surface electrocardiogram (lead I) and His bundle recording before radiofrequency application (*left*) and 30 minutes after the last application (*right*). Note the marked increase of the PQ interval caused by prolongation of the AH interval from 60 to 240 ms. A = atrial potential; H = His bundle potential; HIS = His bundle electrogram; V = ventricular potential.

The QT interval and the HV interval remained unchanged at 355 and 45 ms, respectively (Figures 1 and 2). Anterograde AV nodal effective refractory period and Wenckebach cycle length also increased (415 and 405 ms, respectively).

At the end of the procedure atrial fibrillation was induced by high right atrial stimulation. The ventricular rates now ranged from 75 to 135 beats/min. Because of the marked prolongation of the PQ and AH intervals during sinus rhythm and the slower ventricular rates during atrial fibrillation the procedure was terminated at this point. It was assumed that the impairment of AV nodal conduction by radiofrequency energy was sufficient to alleviate the patient's symptoms. She was referred to the intensive care unit where cardiac rhythm was monitored for another 48 hours. Atrial fibrillation was continuously present during this time, with maximal ventricular rates of 140 beats/min.

Delivery of radiofrequency energy was painless and could be performed without general anesthesia.

At the first clinical follow-up visit 1 month after AV nodal modulation, the patient was asymptomatic without antiarrhythmic medication. The 12-lead electrocardiogram showed a regular sinus rhythm with first-degree AV nodal block and complete right bundle branch block. During 24-hour long-term electrocardiography several episodes of intermittent atrial fibrillation, lasting for up to 30 minutes with maximal ventricular rates of 135 beats/min, occurred but the patient remained asymptomatic. On 2-dimensional echocardiography there was neither evidence of functional impairment of the ventricles nor right atrial thrombus formation. Laboratory tests showed no abnormal findings. The patient took oral acetylsalicylic acid for another 2 months.[4]

This report describes the successful modulation of AV nodal conduction by radiofrequency current in man. Prolongation of AV nodal refractoriness by radiofrequency application to the AV node led to marked symptomatic improvement in a patient with intermittent, drug-refractory atrial fibrillation and rapid ventricular response. Because this procedure resulted in first-degree AV nodal block without any evidence of progression to higher degrees of conduction block, no pacemaker was implanted.

The application of radiofrequency energy may prove to be a suitable and safe therapeutic measure for modulation of AV nodal conduction in patients with medically intractable supraventricular arrhythmias. The reproducibility of creating partial AV nodal block by radiofrequency current needs to be established in a larger patient population.

LOPID®
(gemfibrozil capsules, USP) 300 mg

Before prescribing, please see full prescribing information. A Brief Summary follows:

CLINICAL PHARMACOLOGY. LOPID is a lipid regulating agent which lowers elevated serum lipids primarily by decreasing serum triglyceride with a variable reduction in total serum cholesterol. These decreases occur primarily in the very low density lipoprotein (VLDL) fraction and less frequently in the low density lipoprotein (LDL) fraction. It has been reported that LOPID may increase levels of high density lipoprotein (HDL) subfractions, HDL_2 and HDL_3 as well as apolipoproteins AI and AII. Epidemiological studies have shown that both low HDL-cholesterol and high LDL-cholesterol are independent risk factors for coronary heart disease. It is not yet known whether pharmacological interventions designed to raise HDL-cholesterol alter morbidity or mortality due to coronary heart disease.

The mechanism of action has not been definitively established. In man, LOPID has been shown to inhibit peripheral lipolysis and to decrease the hepatic extraction of free fatty acids, thus reducing hepatic triglyceride production. LOPID inhibits synthesis and increases clearance of VLDL carrier apolipoprotein B, leading to a decrease in VLDL production.

Animal studies suggest that LOPID may, in addition to elevating HDL cholesterol, reduce incorporation of long-chain fatty acids into newly formed triglycerides, accelerate turnover and removal of cholesterol from the liver, and increase excretion of cholesterol in the feces.

LOPID is well absorbed from the gastrointestinal tract after oral administration. Peak plasma levels occur in one to two hours with a plasma half-life of 1.5 hours following multiple doses. Plasma levels appear proportional to dose and do not demonstrate accumulation across time following multiple doses.

LOPID mainly undergoes oxidation of a ring methyl group to successively form a hydroxymethyl and a carboxyl metabolite. Approximately seventy percent of the administered human dose is excreted in the urine, mostly as the glucuronide conjugate, with less than 2% excreted as unchanged gemfibrozil. Six percent of the dose is accounted for in the feces.

In a large, controlled multicenter trial of 427 patients, lipid and lipoprotein changes from average baseline (%) by hyperlipoproteinemic (HLP) type are summarized below for those patients receiving gemfibrozil, 1200 mg/day, at the end of 12 weeks.

HLP Type	TRIGLYCERIDE	CHOLESTEROL				RATIO: HDL Cholesterol / Total Cholesterol
		Total	VLDL	LDL	HDL	
IIa	−44%	−4.2%	−44.3%	−5.8%	+24.6%	+33%
IIb	−45%	−8.6%	−45.0%	−6.4%	+19.5%	+34%
IV	−40%	−1.8%	−40.8%	+14.6%	+17.4%	+23%

INDICATIONS AND USAGE. The initial treatment for hyperlipidemia is dietary therapy specific for the type of hyperlipoproteinemia. Drug therapy should not be used for the routine treatment of elevated blood lipids for the prevention of coronary heart disease. Excess body weight and excess alcoholic intake may be important factors in hypertriglyceridemia and should be addressed prior to any drug therapy. Physical exercise can be an important ancillary measure. Contributory diseases such as hypothyroidism or diabetes mellitus should be looked for and adequately treated. The use of drugs should be considered only when reasonable attempts have been made to obtain satisfactory results with nondrug methods. If the decision is to use drugs, the patient should be instructed that this does not reduce the importance of adhering to diet.

Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, and the adverse findings with clofibrate in two large clinical studies (see Warnings), use of gemfibrozil should be restricted to the following indications.

LOPID may be considered for the treatment of adult patients with very high serum triglyceride levels (type IV or type V hyperlipoproteinemia) who present a risk of abdominal pain and pancreatitis and who do not respond adequately to a determined dietary effort to control them. Patients with triglyceride levels in excess of 750 mg per deciliter are likely to present such risk. LOPID has little effect on elevated cholesterol levels in most subjects. A minority of subjects show a more pronounced response. Therefore, the physician should be very selective and confine gemfibrozil treatment to patients with clearly defined risk due to severe hypercholesterolemia (eg, individuals with familial hypercholesterolemia starting in childhood) who inadequately respond to appropriate diet and more effective cholesterol-lowering drugs.

LOPID is not useful for the hypertriglyceridemia of Type I hyperlipidemia.

The biochemical response to gemfibrozil is variable, and it is not always possible to predict from the lipoprotein type or other factors which patients will obtain favorable results. It is essential that lipid levels be assessed and that the drug be discontinued after three months in any patient in whom lipids do not show significant improvement.

The effect of gemfibrozil-induced reduction of serum cholesterol or triglyceride levels or elevation of HDL cholesterol levels on morbidity or mortality due to coronary heart disease has not been established. Several years may be required before ongoing long-term investigations will resolve this question.

CONTRAINDICATIONS. 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease. (See Warnings).

3. Hypersensitivity to gemfibrozil.

WARNINGS. 1. Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization, 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant 36% higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to noncardiovascular causes, including malignancy, postcholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

2. Long-Term Toxicity and Animal Tumorigenicity Studies – Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant (p greater than 0.05). There were no statistically significant differences from controls in the incidence of liver tumors in female rats, and in male and female mice.

Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following LOPID (gemfibrozil capsules, USP) administration to the male rat. Similar changes have not been found in the human liver.

Male rats had a dose-related increase of benign Leydig cell tumors. Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of the high dose males.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and liver and interstitial cell testicular tumors were increased in male rats, LOPID should be administered only to those patients described in the Indications and Usage Section. If a significant serum lipid response is not obtained, LOPID should be discontinued.

4. Cholelithiasis – LOPID may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected gallbladder studies are indicated. LOPID (gemfibrozil capsules, USP) therapy should be discontinued if gallstones are found.

5. Concomitant Anticoagulants – Caution should be exercised when anticoagulants are given in conjunction with LOPID. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

PRECAUTIONS. 1. **Initial Therapy** – Before instituting LOPID therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and other medical problems such as diabetes mellitus and hypothyroidism.

2. **Continued Therapy** – Pretreatment laboratory studies should be performed to ensure that patients have abnormal levels of serum lipids. Periodic determinations of serum lipids should be obtained during LOPID administration. The drug should be withdrawn after three months if the lipid response is inadequate.

3. **Impairment of Fertility** – Administration of approximately three and ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to their offspring.

4. **Pregnancy Category B** – Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 6.7 times the human dose. These studies have revealed no evidence of impaired fertility in females or harm to the fetus due to LOPID. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that LOPID is tumorigenic in male rats, the use of LOPID in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

5. **Nursing Mothers** – Because of the potential for tumorigenicity shown for gemfibrozil in male rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

6. **Hematologic Changes** – Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of LOPID therapy. However, these levels stabilize during long-term administration. Therefore, periodic blood counts are recommended during the first 12 months of LOPID administration.

7. **Liver Function** – Abnormal liver function tests have been observed occasionally during LOPID administration, including elevations of SGOT, SGPT, LDH, and alkaline phosphatase. These are usually reversible when LOPID is discontinued. Therefore periodic liver function studies are recommended and LOPID therapy should be terminated if abnormalities persist.

8. **Use in Children** – Safety and efficacy in children have not been established.

ADVERSE REACTIONS. In controlled clinical trials of 805 patients, including 245 who received LOPID for at least one year, the most frequently reported adverse reactions associated with LOPID involved the gastrointestinal system. In decreasing order of frequency, these were abdominal pain (6.0%), epigastric pain (4.9%), diarrhea (4.8%), nausea (4.0%), vomiting (1.6%), and flatulence (1.1%). Other adverse reactions where the probability of a causal relationship to LOPID (gemfibrozil capsules, USP) therapy exists are listed by system.

Integumentary: rash, dermatitis, pruritus, urticaria

Central Nervous System: headache, dizziness, blurred vision

Musculoskeletal: painful extremities

Hematopoietic: anemia, eosinophilia, leukopenia

Other reactions have been reported under conditions where a causal relationship is difficult to establish, thus the physician should be alert to these occurrences. Reports of viral and bacterial infections (common cold, cough, and urinary tract infections) were more common in gemfibrozil than in placebo-treated patients.

Other reactions were:

Gastrointestinal: dry mouth, constipation, anorexia, gas pain, dyspepsia

Musculoskeletal: back pain, arthralgia, muscle cramps, myalgia, swollen joints, myositis

Central Nervous System: vertigo, insomnia, paresthesia, tinnitus

Clinical Laboratory: hypokalemia, liver function abnormalities (increased SGOT, SGPT, LDH, CPK, alkaline phosphatase)

Miscellaneous: fatigue, malaise, syncope, alopecia

DOSAGE AND ADMINISTRATION. The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meal. Some patients will experience therapeutic effects on 900 mg/day; a few may require 1500 mg/day for satisfactory results.

DRUG INTERACTIONS. CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID. THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

MANAGEMENT OF OVERDOSAGE. While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

Caution – Federal law prohibits dispensing without prescription.

No one else can put
an entire body
of medical knowledge
before you A.S.A.P.

As soon as Polaroid.

In the medical field today, it's not enough to get the job done right. It must be done right away. Nowhere is this more apparent than in the area of medical imaging.

Whether it's for documentation, referral, presentations, research, or patient education, the need for fast, accurate and high quality imaging is essential to the practice of good medicine.

Which is where Polaroid instant images fit into the picture.

Because when you or your colleagues say you need images A.S.A.P., you don't mean as soon as possible.

What you really mean is As Soon As Polaroid instant images.

QUALITY A.S.A.P.

Polaroid instant photographic images are often indistinguishable from those that take hours or days to get by conventional wet-process methods. You'll find with Polaroid films you can capture even the smallest details of your subjects. And we're so confident of their quality we offer you Polaroid's Image Guarantee – if you're not satisfied, for whatever reason, with the image you get, we'll replace your film free.*

SIMPLICITY A.S.A.P.

Polaroid films are so quick to use partly because they're so simple to use. There's no need for darkrooms, special facilities, or photographic staff. In most cases, Polaroid instant imaging is no more complicated than pushing a button or pressing a foot pedal. You can take images that eject and develop automatically – with no pulling, timing, or peeling.

STABILITY A.S.A.P.

Polaroid instant films give you the stability you need without the wait. Polaroid instant color and black and white prints are highly stable and are far superior in quality and stability to thermal prints. In fact, Polaroid sheet and pack films, when stored properly, deliver image stability comparable to conventionally-processed photographic prints.

SERVICE A.S.A.P.

Because we're imaging professionals, with more than forty years of experience in the medical field, we're in a unique position to diagnose your photographic needs and provide you with imaging solutions that no one else can. What's more, we back up these solutions with service that includes a technical assistance toll-free hotline so you and your staff can get answers to virtually any technical question instantly.

Quality. Simplicity. Stability. Service. Some may be able to deliver a couple of them. A select few can deliver all of them. But only one – Polaroid – can deliver them all A.S.A.P.

A.S.A.P.

Polaroid offers you more than forty different instant film types – color or black and white, print or 35mm slide films, and overhead transparencies – everything you need for documentation, presentation, publication, referrals and patient records.

What's more, Polaroid offers you a complete range of instant imaging systems, including close-up cameras, copy stands, and electronic imaging systems for recording from video sources and personal computers.

In many cases, instant imaging equipment has been developed by working hand-in-hand with leading medical and scientific equipment manufacturers. The results are instant imaging systems specifically designed for the latest diagnostic and research instruments.

And you get it all A.S.A.P. – As Soon As Polaroid.

Polaroid instant images. If you're not using them, you're missing instant access to an entire body of medical knowledge.

Sudden Death and Cardiomegaly Unassociated with Coronary, Valvular, Congenital or Specific Myocardial Disease

AMY H. KRAGEL, MD
WILLIAM C. ROBERTS, MD

Sudden death has many causes and necropsy usually allows delineation of the specific cause.[1] During the past 8 years we have studied at necropsy 6 patients, all men, who died suddenly outside the hospital and although necropsy disclosed cardiomegaly, a specific cause of death was not discernible. Certain clinical and morphologic features in these 6 patients are described in this report.

All 6 patients (Table I) died outside the hospital and the necropsy in each was performed at the District of Columbia Medical Examiner's Office. In each case the heart was examined initially by one (WCR) of us, subsequently brought to the National Institutes of Health, and later examined by both of us. After accurately weighing the heart, the epicardial coronary arteries were incised transversely to their longitudinal axes at 5-mm intervals. At least 2 sections of left ventricular wall extending from endocardium to epicardium and measuring at least 2 cm in length were processed for histologic study and examined. The records of the Medical Examiner's Office also were examined. The records indicated that only 1 patient (no. 4, Table I) had been hospitalized previously and that a year before death for therapy of systemic hypertension.

The 6 men, all black, ranged in age from 41 to 68 years (mean 49). Three (numbers 4 through 6, Table I) had historic evidence of "high blood pressure" in the past and 1 (no. 4) took an antihypertensive medicine (diuretic). Two patients (numbers 4 and 6) also were known to have received digitalis therapy; patient 4 had had a single episode of pulmonary edema, which was thought to be secondary to severe systemic hypertension, about 1 year before death. No evidence of congestive heart failure was present in the other 4 patients. Two patients (numbers 3 and 4) were known to be habitual alcoholics. None were known cocaine or opiate addicts. The circumstances of death were the following: 4 patients (numbers 1 through 4) were found dead after having been seen alive and well within the previous 6 hours; the other 2 died instantaneously or nearly so (while in a coffee shop during a work break [no. 5]; after his first seizure while walking on the sidewalk [no. 6]).

Toxicologic studies (including screening tests performed on blood, bile and lung tissue for over 300 drugs including volatile alcohols, narcotics, antihistamines, phenothiazines, barbiturates, synthetic narcotics, various sedatives and cocaine) were performed at necropsy in 5 patients: in 4 patients results of all studies were negative; in 1 patient (no. 1) the blood alcohol level was 50 mg/dl (>100 mg/dl is legally intoxicated). The weight of the heart ranged from 440 to 700 g (mean 569). Body weight ranged from 63 to 104 kg (mean 87). Heart weight as a percent of body weight ranged from 0.51 to 0.98 (mean 0.69) (normal 0.42 to 0.46). Their height ranged from 165 to 193 cm (mean 178). The epicardial surface was smooth in each case. The subepicardial adipose tissue was increased in 5 patients. The coronary arteries arose and coursed normally in all 6 patients. The sizes of the coronary ostia appeared normal in all 6 patients. In 4 patients the right coronary artery was dominant; in 1 patient, the left circumflex artery was dominant and in 1 patient both right and left circumflex arteries coursed to the crux (codominant). The lumens of the epicardial coronary arteries were completely or virtually devoid of atherosclerotic plaques or other material. The 4 valves in each patient were normal or virtually normal. No foci of grossly visible myocardial fibrosis or necrosis or other lesions were present in any heart. Both atrial and ventricular septa were intact in all 6 patients. No intracardiac thrombi or mural endocardial plaques were present in any of the 4 cardiac chambers in any of the 6 patients.

The liver ranged in weight from 1,810 to 2,660 g (mean 2,303). No patient had evidence of hepatic cirrhosis. The spleen ranged in weight from 140 to 390 g (mean 222) and all appeared normal upon gross inspection. No grossly visible lesions were found in the lungs in any patient. The brain grossly appeared normal in 5 patients; in 1 (no. 4), 3 small healed cortical infarcts were observed. The kidneys appeared normal in 4 patients and in 2 patients (numbers 5 and 6) showed changes most compatible with those secondary to systemic hypertension. Patient no. 3 had changes of chronic pancreatitis. The ascending aorta was normal in 5 patients and in 1 (no. 3) large atherosclerotic plaques were present focally in the tubular portion of ascending aorta. The latter patient's coronary arteries, in contrast, were virtually free of atheroslcerotic plaques.

Sections of myocardium showed variable degrees of myocyte hypertrophy and interstitial fibrosis. There were no foci of myocardial necrosis or large

TABLE I Certain Findings in the 6 Men

Pt No.	Age (yrs)	Body Weight (kg)	Height (cm)	Heart Weight (g)	Heart Weight as Percent of Body Weight	Dilatation (0 to 3+) RV	LV
1	41	104	185	680	0.65	0	0
2	44	84	178	440	0.51	0	0
3	45	63	168	515	0.61	0	0
4	46	97	180	620	0.98	1+	2+
5	50	73	165	460	0.63	0	0
6	68	92	193	700	0.76	2+	2+

LV = left ventricle; RV = right ventricle.

areas of replacement fibrosis or presence of inflammatory cells or other abnormal infiltrates in the myocardial walls. No foci of myofiber disarray were observed in sections of ventricular septa. The intramural coronary arteries were normal.

The most likely cause for the cardiomegaly in our 6 patients is systemic hypertension. Systemic arterial pressure was available in only 3 of the 6 patients and in each it was stated to have been elevated. None of the 6 patients had narrowing of any epicardial coronary artery, none had anatomic evidence of valvular, myocardial, congenital or pericardial heart disease. None had a coronary arterial anomaly. Cases of morbid obesity (>250 pounds) were excluded from this study.[2] Although it is well recognized that patients with systemic hypertension have an increased frequency of both atrial and ventricular arrhythmias compared with normotensive persons and that hypertensive persons with left ventricular hypertrophy have a higher frequency of these arrhythmias compared with hypertensive persons without left ventricular hypertrophy,[3,4] the occurrence of sudden death in persons with systemic hypertension in the absence of significant narrowing of 1 or more epicardial coronary arteries has not been described previously to our knowledge.

Percutaneous Double Balloon Valvotomy for Rheumatic Tricuspid Stenosis

PAULO A. RIBEIRO, MD
MUAYED AL ZAIBAG, MRCP
SAAD AL KASAB, MRCP
MOHAMED IDRIS, MRCP
MURTADA HALIM, MRCP
MOHEEB ABDULLAH, MRCP
MAIE SHAHED, MRCP

We attempted tricuspid balloon valvotomy in 4 selected consecutive symptomatic patients (2 male and 2 female) (mean age 41 years), with severe tricuspid stenosis (TS) and mild mitral valve disease. The immediate and short-term results are reported. To define the physiologic effects of balloon tricuspid valvotomy, we studied the cardiac output of these patients at rest and during treadmill exercise, both before and after the procedure.

Written informed consent was obtained from all patients. Oral premedication was 10 mg of diazepam. Aortic pressure monitoring was achieved by inserting an 18-gauge cannula into the right femoral artery in patient 1 and by a 7Fr pigtail catheter inserted into the descending aorta in patients 2, 3 and 4. A 7Fr Berman angio catheter was passed from each femoral vein to measure the pressure gradient across the tricuspid valve and to perform a right ventricular angiogram before and after balloon inflation. After calibration and the recording of identical simultaneous right atrial pressure tracings from both catheters, one of them was advanced to the right ventricular cavity. To measure the gradient across the tricuspid valve, 10 consecutive cardiac cycles were recorded at a paper speed of 100 mm/s. The 0.038-inch Teflon-coated exchange guidewires (250 cm long) with preshaped curved tips were then advanced through two 7Fr pigtail catheters, which previously had been inserted percutaneously in each femoral vein; the end of each guidewire was positioned at the apex of the right ventricle (Figure 1). A 9Fr balloon catheter (Meditech), 15 to 20 mm diameter and 3 cm length, was advanced percutaneously over each guidewire and positioned across the tricuspid valve under fluoroscopic control in the 10° right anterior oblique projection; the correct position was confirmed by fluoroscopic detection of the indenta-

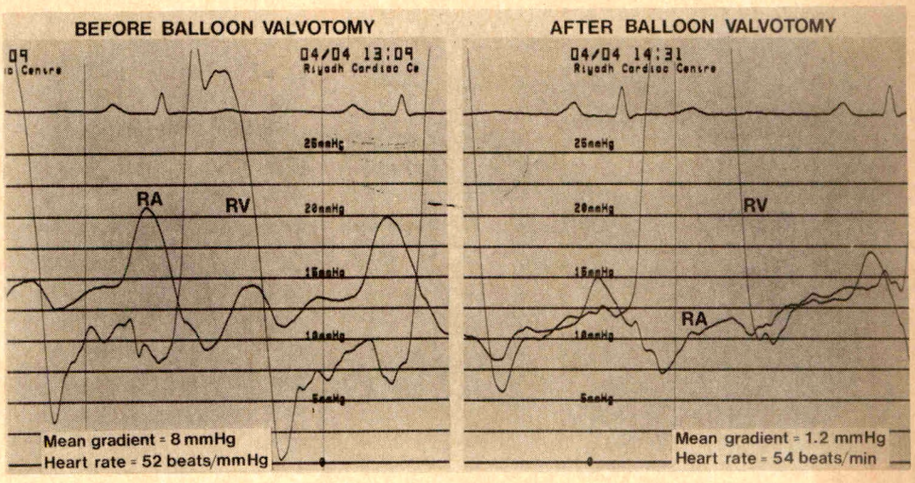

FIGURE 2. Right atrial (RA) right ventricular (RV) pressure gradient recording before and immediately after successful tricuspid balloon valvotomy in patient 4.

tion of the balloon during inflation. The balloons were inflated simultaneously to a maximum pressure of 5 atmospheres. A successful valvotomy was judged at the time by the loss of balloon indentation and confirmed by hemodynamic measurement (Figures 1 and 2). By these criteria, patients 1 and 2 required the use of larger sized balloons to achieve a successful result (Table I). The balloons were inflated for 8 to 12 seconds, and during this time the systolic arterial pressure remained above 80 mm Hg. The number of inflations ranged from 3 to 13 to achieve optimal balloon alignment across the stenotic tricuspid valve.

The study protocol included cardiac catheterization and 2-dimensional echocardiography, using a Hewlett Packard system, before the procedure, immediately after and again at 8- to 20-week follow-up. Treadmill exercise testing was performed in patients 2, 3 and 4, using a Marquette system, before valvotomy and at the 8- to 20-week follow-up. The cardiac output was measured at rest and 2 to 3 times during each stage of the exercise test by the thermodilution technique and measurements were repeated using the green dye method in patients 2 and 3, who had tricuspid regurgitation.

After tricuspid double balloon valvotomy the tricuspid valve area increased from 0.75 ± 0.1 to 1.8 ± 0.5 cm^2 ($p < 0.05$) (Table I). Angiographically there was no increase in the degree of tricuspid regurgitation in any of the 4 patients. Before balloon valvotomy, all 3 leaflets of the tricuspid valve were thickened, with restricted motion and diastolic doming. With real-time 2-dimensional echocardiography after valvotomy, doming persisted. There was some improvement in the motion of the anterior tricuspid leaflet in all 4 patients, of the posterior leaflet in 2 patients and of the septal leaflet in 1 patient (Figure 3). The 8- to 20-week follow-up hemodynamic studies showed a persistent 150% increase in tricuspid valve area to 1.9 ± 0.6 cm^2. There was a marked increase in resting cardiac output after tricuspid balloon valvotomy, from 2.5 ± 0.6 to 3.6 ± 1 liters/min ($p < 0.02$). At peak treadmill exercise there was an increase in cardiac output from 5.6 ± 1.4 to 7.4 ± 1.1 liters/min ($p < 0.01$) at similar heart rates. All patients reported symptomatic improvement, with

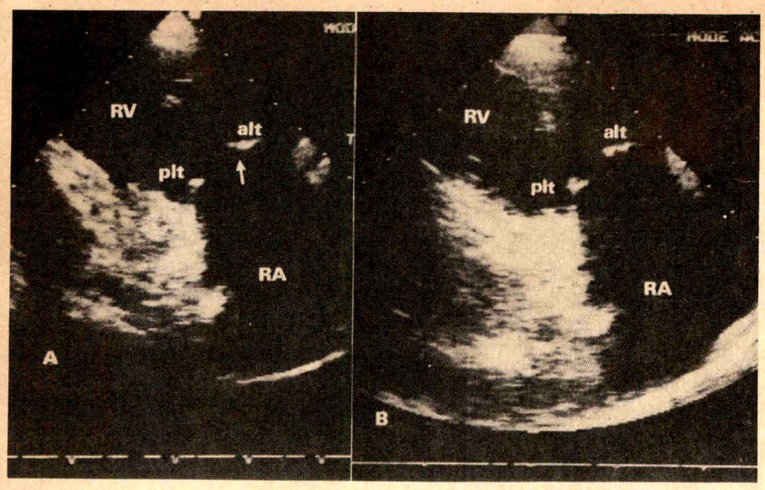

FIGURE 3. *A* and *B*. Parasternal right ventricular inflow view (diastolic frame). Note in tricuspid leaflet separation after successful balloon tricuspid valvotomy in patient 2. Alt = anterior leaflet of tricuspid valve; plt = posterior leaflet of tricuspid valve; RA = right atrium; RV = right ventricle.

virtual disappearance of fatigue and shortness of breath on exertion. The diastolic rumble disappeared in all 4 patients.

Our findings demonstrate unequivocally the feasibility of percutaneous double balloon tricuspid valvotomy for the relief of severe rheumatic TS. The 150% increase in tricuspid valve area after balloon valvotomy, together with the marked reduction in tricuspid valve gradients, persisted in short-term follow-up.

The major hemodynamic disturbance in TS is reduction in cardiac output.[1] In contrast to results of a mitral valve study,[2] we demonstrated that after tricuspid balloon valvotomy there was a significant increase in cardiac output both at rest and during treadmill exercise testing. These findings accord with the patients' symptomatic improvement.

Both this study and our initial case report[3] indicate that maximal tricuspid valve areas are achieved by balloon valvotomy with a 15 + 20, or 18 + 20 mm balloon combination, without inducing tricuspid regurgitation. We do not advocate balloon valvotomy in patients with significant tricuspid regurgitation; 2 of our patients (2 and 3) had angiographically moderate tricuspid regurgitation, although this was hemodynamically not significant as assessed by the mean right atrial pressure and V-wave amplitude (Table I).

The improvement in tricuspid valve area results achieved with our percutaneous double balloon valvotomy technique are comparable to those reported after surgical tricuspid valvotomy[4]; however, we had no morbidity or mortality. This technique is suitable not only in patients with pure severe TS but also for patients with concomitant severe rheumatic mitral and tricuspid stenosis.

Clinical Features of Mitral Valve Prolapse Associated with Low Body Weight

RICHARD B. DEVEREUX, MD
ROGER CAPPUCCI, BS
RANDI KRAMER-FOX, MS

An association between mitral valve prolapse (MVP) and low body weight has been well documented in family,[1] general population,[2] and clinical[3] studies. The low body weight of patients with MVP may exert a clinically beneficial effect by permitting lower levels of blood pressure in MVP patients than in comparable control subjects.[1,4] The observation of a low prevalence of mitral clicks or murmurs in MVP patients, however, in 2 studies in which MVP was strongly associated with low body weight[2,5] has led some investigators to suggest that MVP in lean patients might represent a variant of normal devoid of the auscultatory features encountered in patients with clinically recognized MVP. To test this hypothesis, we related body habitus to auscultatory and other demographic and clinical features of MVP in consecutive adult family members documented to have MVP in a family study that has been previously reported in part.[1,6–7]

The 105 family members with MVP included 67 women and 38 men, aged 16 to 79 years (mean 36); 95

TABLE I Clinical Findings in Mitral Prolapse Subjects Grouped by Body Mass Index

	Group I (n = 35)	Group II (n = 35)	Group III (n = 35)
Body mass index (kg/m^2)	15.01–20.32	20.38–22.14	22.19–37.46
Age (yr)	30 ± 14‡	34 ± 15	44 ± 16‡
Female: No. (%)	27 (77)	23 (66)	17 (49)
Peak systolic blood pressure (mm Hg) (%)	118 ± 13*	122 ± 16	129 ± 22*
End-diastolic blood pressure (mm Hg) (%)	73 ± 6†	77 ± 9	80 ± 10†
Midsystolic precordial clicks (%)	9 (26)	9 (26)	13 (37)
Late systolic precordial murmurs (%)	5 (14)	5 (14)	2 (6)
Click and murmur (%)	10 (29)	5 (14)	2 (6)
Long/holosystolic murmur (%)	1 (3)	1 (3)	2 (6)
Any typical auscultatory feature (%)	25 (71)	20 (57)	19 (54)
"Silent" or midsystolic murmur (%)	10 (29)	15 (43)	16 (46)

Statistical significance, group I compared with group III: * $p < 0.02$; † $p < 0.005$; ‡ $p < 0.0005$.

were first-degree relatives of probands with clinically recognized MVP, 7 were second-degree relatives and 3 were spouses of probands or family members. MVP was diagnosed by M-mode and cross-sectional echocardiography using previously described criteria.[7] *Weight and height were recorded and used to calculate body mass index as the ratio of weight in kilograms/(height in meters).*[2] *Auscultation was performed in multiple positions and with isometric handgrip exercise by an investigator without knowledge of echocardiographic findings. Subjects were divided into 3 groups of 35 subjects each based on body mass index, with values of 15 to 20.3 kg/m^2 in group I, 20.4 to 22.1 kg/m^2 in group II and 22.2 to 37 kg/m^2 in group III. Statistical comparison between groups with lowest and highest body mass index was performed with unpaired Student t tests for continuous variables and the chi-square test, with Yates' continuity correction when appropriate for proportions. The statistical independence of relations between blood pressure and body mass index and age was assessed by stepwise multiple linear regression analysis.*

Demographic and clinical findings in the 3 groups are listed in Table I. Overall body mass index was below 22.7, the mean value corresponding to 1983 Metropolitan Life Insurance Co. ideal body weight,[8] *in 75 of 105 (71%) subjects with MVP. The group with lowest body mass index was disproportionately female (77%) compared with that with highest body mass index (49%) (chi-square = 6.47, $p < 0.02$), with an intermediate sex distribution in the middle tercile. Progressive increases in age and systolic and diastolic blood pressures occurred from the group with lowest to that with highest body mass index. Multiple linear regression analysis revealed highly significant ($p < 0.001$) correlations between age and systolic and diastolic pressures whereas independent correlations between body mass index and blood pressure levels approached but did not attain statistical significance.*

Midsystolic clicks occurred in isolation in 9 of 35 patients (26%) in the lower 2 terciles of body mass index and in 13 of 35 (37%) of the group with highest body mass index. Late systolic murmurs occurred alone or in combination with midsystolic clicks in 43% of subjects in group I, 26% of subjects in group II and 12% of group III (chi-square = 7.22, $p < 0.01$ vs group I). Typical auscultatory features of MVP were observed in more subjects with MVP in group I (71%) than in those in the other 2 groups (57% and 54%). Mitral clicks, murmurs or both were equally prevalent in men (63%) and women (60%).

These results indicate that MVP subjects with relatively low body weight have at least as high a prevalence of mitral systolic clicks and murmurs as those with body weight in the average normal to elevated range in relation to height. This finding is opposite to that predicted by the hypothesis that echocardiographic MVP associated with low body weight is a "variant of normal" unassociated with typical auscultatory features of MVP, and suggests that this hypothesis is incorrect. Our data support the view that lean subjects with inherited MVP also have blood pressure levels that are, on average, slightly lower than expected. Because only 4 subjects, at least 1 in each group, had holosystolic or nearly holosystolic murmurs of mitral regurgitation associated with left ventricular or left atrial dilatation, we are unable to determine whether the likelihood of developing hemodynamically important mitral regurgitation is related to body habitus in subjects with MVP. The older age and slight male predominance of the group with higher body mass index in the present study resembles the older age and male predominance we have previously found to characterize MVP patients with severe mitral regurgitation.[9] This suggests that this complication of MVP may be concentrated in MVP patients whose phenotype does not include a lean body habitus.

Further examination of our data reveals that the modest decrease in prevalence of auscultatory features among the MVP subjects with highest body mass index is due entirely to a strikingly lower prevalence of late systolic murmurs compared with lean subjects with MVP (12 vs 43%) that is not fully offset by a modest increase in the proportion of individuals who had isolated mitral systolic clicks (38 vs 26%). The greater chest wall thickness in less lean individuals with MVP might "damp" transmission to the chest

surface of soft systolic murmurs more than of higher intensity systolic clicks. The fact that almost all late systolic murmurs in our patients were of grade I or II/VI intensity is in accord with this possibility.

Echocardiographic Evaluation of Obstructive Mechanism of Tetralogy of Fallot with Restrictive Ventricular Septal Defect

NORMAN N. MUSEWE, MB, ChB
JEFFREY F. SMALLHORN, MBBS
C.A.F. MOES, MD
ROBERT M. FREEDOM, MD
GEORGE A. TRUSLER, MD

Despite the trend toward earlier total surgical correction of tetralogy of Fallot, a number of complicating factors, most often related to unfavorable pulmonary arterial anatomy,[1] and, rarely, reduced left ventricular size,[2] may make palliation with a systemic to pulmonary arterial anastomosis necessary before corrective surgery. A restrictive ventricular septal defect (VSD) complicating tetralogy of Fallot is one of the less well-recognized features associated with a high mortality when surgical repair is delayed beyond infancy.[3-11] The echocardiographic recognition of this anomaly should be of importance because of the trend toward use of noninvasive diagnostic modalities in infants with various forms of congenital heart disease.[12] This study reviews echocardiographic features of tetralogy of Fallot in patients with a documented restrictive VSD, and examines the contribution of clinical findings to the diagnosis of this entity. The progression over time of VSD restriction and its impact on surgical management are also assessed.

From July 1983 to July 1987 a total of 80 new cases of tetralogy of Fallot were seen at the Hospital for Sick Children. Of these, 5 patients were identified as having a restrictive VSD during routine echocardiography. This time period was chosen because it coincided with the introduction of high resolution imaging and Doppler ultrasound at this institution. Four of the 5 patients had hemodynamic, angiographic and surgical confirmation of VSD restriction, with additional necropsy confirmation in 1. The fifth patient, who will be undergoing hemodynamic evaluation and surgery,

* high velocity unresolved; † data obtained during infusion of prostaglandin E_1.

had VSD restriction defined by a high velocity Doppler jet from the right ventricle across the VSD. The remaining 75 cases had no evidence of VSD restriction as defined by echocardiographic, Doppler, hemodynamic or surgical evaluation.

The clinical features of each of the 5 patients were examined in an attempt to identify common features that might permit differentiation from those without VSD restriction. Where cardiac catheterization was carried out, hemodynamic measurements and angiocardiograms were examined and compared with echocardiographic findings. Anatomic features of VSD restriction obtained from surgical or necropsy records were also compared with the findings at echocardiography.

Serial echocardiograms were examined beginning with the earliest study that was available. These were performed using either the Hewlett Packard 77020 or ATL Utramark 8 ultrasound systems, both equipped with image-directed Doppler ultrasound. The VSD was evaluated from the subcostal and parasternal long- and short-axes, and the apical 5-chamber view. In addition to these views, the subxiphoid right oblique view[13] was used in 3 patients. Doppler flow velocities across the right ventricular outflow tract and the VSD were also evaluated. The degree of right ventricular hypertrophy, assessed by measurement of the dimension of the right ventricular free wall, was compared with measurements obtained in 5 age-matched patients of tetralogy of Fallot without evidence of VSD restriction. The ratio of right and left ventricular end-diastolic dimensions in the parasternal short-axis view in patients was also compared to that in the 5 control patients.

Mean age at diagnosis of the major cardiac lesion was 2 weeks. Cyanosis was recognized at a mean age of 7 weeks (range 1 to 28), and was graded as mild in 4 patients. One patient had cyanotic spells by 3 months of age. Electrocardiographic evidence of severe right ventricular hypertrophy with strain (inverted T waves and depressed ST segments) was present in 1 patient only (patient 4). None of the patients exhibited clinical signs of right-sided heart failure.

The data from the 4 patients who underwent cardiac catheterization are listed in Table I. Angiographically, the mode of VSD restriction was felt to be tricuspid septal leaflet or accessory tissue tags in each (Figure 1).

At surgery in 4 patients, accessory tricuspid valve tissue was noted inserting into the posterior and superior margins of the perimembranous malalignment ventricular septal defect, close to the aortic valve anu-

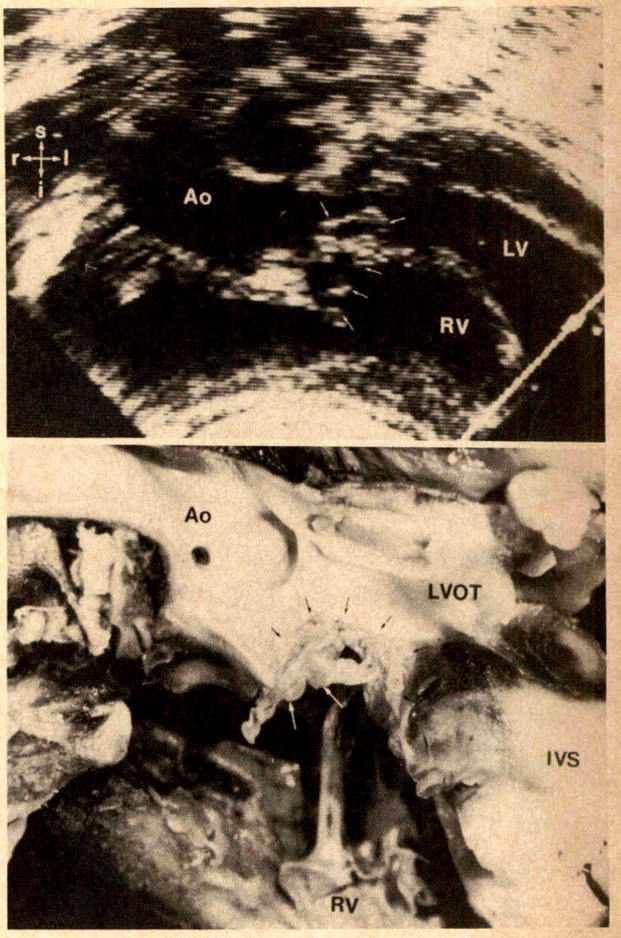

FIGURE 2. Two-dimensional echocardiographic-pathologic correlation of restrictive ventricular septal defect in patient 4. Subcostal long-axis view showing tricuspid tissue (*arrows*) protruding into left ventricular outflow tract (*top*). The same appearance is shown in the pathologic specimen (*bottom*). Ventricular septal defect margins are indicated by the *small arrows*. The ventricular septal defect patch is removed to facilitate visualization of accessory tricuspid tissue, which is seen attached to the superior margin of the ventricular septal defect (*large arrows*). Abbreviations as in Figure 1.

TABLE II Echocardiographic Measurements of Right Ventricular (RV) Free Wall Thickness and the Ratio of Right to Left Ventricular End-Diastolic Dimensions in Patients and Five Age-Matched Control Cases of Tetralogy of Fallot Without Ventricular Septal Defect Restriction

Pt No.	RV anterior wall thickness (mm)		RVED/LVED	
	P	C	P	C
1	10	4	.96	.61
2	7	5	.90	.65
3	6	4	.66	.56
4	5	3.5	1.16	.60
5	8	5	.72	.66

Measurements in patients and controls were performed from the parasternal short-axis view.

C = control; LVED = left ventricular end-diastolic dimension; P = patient; RVED = right ventricular end-diastolic dimension.

lus. Hypertrophied free wall and septal bands were also noted, but the latter did not contribute directly to the VSD obstruction in any of the patients.

Surgical repair involved detachment of the accessory tricuspid tissue from the margins of the defect followed by routine VSD closure in 3, while in the fourth patient, the accessory tissue was not resected, but was sutured to the VSD patch. This 3-day old patient died shortly after surgery. At autopsy, VSD restriction by tricuspid tissue was confirmed (Figure 2).

At least 2 serial 2-dimensional echocardiograms were available in 4 patients. The fifth patient (patient 4) had only 1 study. Data from patients and control cases are listed in Table II. Severe hypertrophy of both the right ventricular free wall and ventricular septum, with increased echodensity of the endocardial surface suggestive of endocardial fibrosis was seen in 1 patient (no. 1). The septal motion was flat in all patients.

In 4 patients, accessory tricuspid tissue was present within the VSD throughout the cardiac cycle. In these patients, the obstructing tissue was attached to the base of the infundibular septum, close to the aortic valve anulus. While this tissue moved anteriorly in diastole in the parasternal short-axis view, it bulged into the left ventricular outflow tract to variable degrees in systole. In 1 patient the accessory tissue protruded into subaortic area throughout the cardiac cycle. The echocardiographic and necropsy appearance in this patient are shown in Figure 2. In the fifth patient (no. 5, Figure 3), in contrast to the other 4, the obstructing tissue showed no attachments to the base of the infundibular septum. This tissue moved away from the VSD in diastole (Figure 3A), leaving it unobstructed, but moved into the VSD in early systole, occluding it until early diastole. (Figure 3B).

The mechanism of VSD obstruction in this patient appeared to involve suctioning of accessory tricuspid tissue into the defect at the onset of ventricular systole. This is further demonstrated in Figure 4, which uses the subxiphoid right oblique view in the same patient.

Obstruction of the VSD was recognized at the first 2-dimensional echocardiographic evaluation in 3 patients. On frame-by-frame review of the initial studies in each of the other 2 patients, the substrate for VSD restriction was already present. In 1 patient (no. 3), tissue could be intermittently seen within the VSD in both the parasternal long- and short-axis views. In this patient, the tissue appeared more obvious at the second study. The other patient (no. 5) had an accessory tricuspid tissue that was not attached to the base of the infundibular septum, but appeared in the VSD only during systole. This phenomenon was present but not recognized at the first study.

The results of Doppler evaluation of the VSD, performed in all patients at the last echocardiographic evaluation, are listed in Table I. Of the 4 patients who had more than 1 echocardiographic evaluation, 2 had serial Doppler performed across the VSD. In 1 (patient no. 1), a high velocity unresolved jet was present at 2 serial Doppler examinations. In the other (patient no. 2) low velocity left to right Doppler flow (2 m/s) was documented across the VSD at 2 earlier studies.

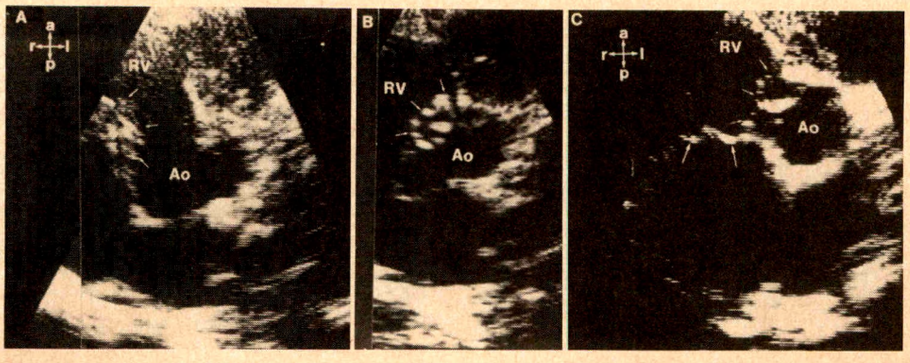

FIGURE 3. *A*, parasternal short-axis view in patient 5. The ventricular septal defect is wide open in diastole; accessory tricuspid tissue is indicated by *arrows*. *B*, the ventricular septal defect in the same patient is completely occluded by accessory tricuspid tissue in early systole. The obstructing tissue in this patient did not have attachments to the superior margin of the ventricular septal defect. *C*, in contrast to the patient shown in A and B, accessory tricuspid tissue was attached to the base of the infundibular septum in this patient (*small arrows*), resulting in its appearance within the defect throughout the cardiac cycle. A systolic frame is shown. The *large arrows* indicate the septal and superior leaflets of the tricuspid valve in a closed position. Abbreviations as in Figure 1.

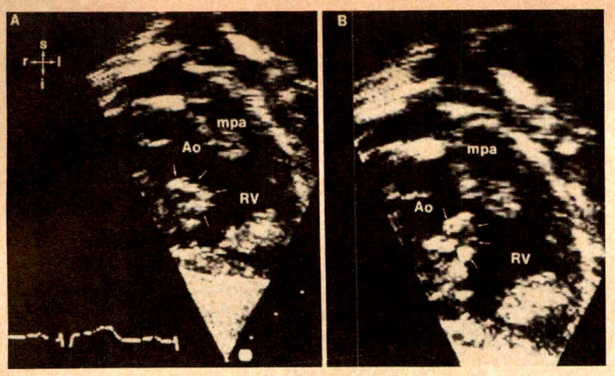

FIGURE 4. *A*, subxiphoid right oblique views in the same patient as in Figure 3 (A and B). In diastole the accessory tricuspid tissue moves away from the ventricular septal defect, leaving it unobstructed (*arrows*). *B*, in ventricular systole, this tissue moves into the ventricular septal defect, almost completely occluding it. Both outlets, the infundibular septum and the ventricular septal defect are well profiled in this view. mpa = main pulmonary artery; other abbreviations as in Figure 1.

At the last study, however, the Doppler flow was right to left.

The first description of a restrictive VSD in tetralogy of Fallot is attributed to Soulié et al[3] in 3 of 22 patients with tetralogy of Fallot and suprasystemic right ventricular pressures. Various other investigators[4–11,14] have subsequently described this uncommon entity.

While earlier reports[4,5] emphasized the clinical signs that might lead to suspicion of this complication in tetralogy of Fallot, they relied almost entirely on the use of phonocardiography for the detection of subtle changes in quality and duration of the systolic ejection murmur to differentiate this entity from classic tetralogy of Fallot. Although Neufeld et al[5] described 3 older patients with forceful right ventricular impulses and distended jugular veins, features not normally seen in tetralogy of Fallot, in most patients clinical features were not helpful in making the diagnosis of a restrictive VSD before cardiac catheterization.

Clinical suspicion of a restrictive VSD may therefore depend on detection of an unusually increased right ventricular precordial impulse or increased jugular venous pressure, signs that may be difficult to elicit in small infants. The finding of severe right ventricular hypertrophy and strain on electrocardiography may be helpful in patients with early severe obstruction to the VSD. In this study, however, we could not identify any consistent clinical features suggestive of VSD restriction.

In most of the reported cases of tetralogy of Fallot or pulmonary atresia,[9] VSD restriction has been due to tricuspid septal leaflet or accessory tissue anomalously inserting into the margins of the defect. VSD restriction due to a truly small defect must be very rare. In the most detailed morphologic description of VSD restriction in tetralogy of Fallot[10] it was divided into "mobile" and "fixed" types, depending on the mobility of the accessory tricuspid tissue. In this study[10] the authors suggested that, because of the possibility of subaortic obstruction, the mobile tissue should be completely excised, or the VSD patch placed such that the accessory tissue is left on the right ventricular aspect of the septum.

In all the patients in this study, restriction was similarly due to accessory tricuspid tissue, and could be potentially recognized by echocardiography as early as the newborn period. It therefore appears that the substrate for VSD restriction, when it occurs, is present as an integral part of the pathology of tetralogy of Fallot.

Careful evaluation of the VSD is essential as the absence of tissue occluding the defect throughout the cardiac cycle does not preclude restriction, as was seen in 1 of our patients. We speculate that in this case, unlike the other 4, a "venturi" type effect played a significant role in suctioning the accessory tissue into the VSD during systole, thereby obstructing it.

When obstructing tissue is not attached to the infundibular septum, specific diagnosis rests on slow frame-by-frame examination of the excursion of accessory tricuspid tissue, because obstruction of the VSD occurring in systole only may be missed during real-time examination, especially at rapid heart rates. Although significant left ventricular outflow obstruction by accessory tricuspid tissue was not present in any of our patients, the surgeon should probably excise this tissue where possible, regardless of its mobility, except where excision might affect the integrity of the tricuspid valve.

Doppler echocardiography plays an important role in identifying VSD restriction. Caution must be taken not to dismiss a potentially restrictive VSD as nonobstructive if the substrate exists in the absence of a documented gradient. In this setting, decompression through a relatively unobstructed right ventricular outflow tract may be responsible for the lack of a pressure difference between the 2 ventricles. It is also possible that the VSD tissue may proliferate in a manner similar to that encountered in perimembranous ventricular septal defects,[15] leading to progressive restriction.

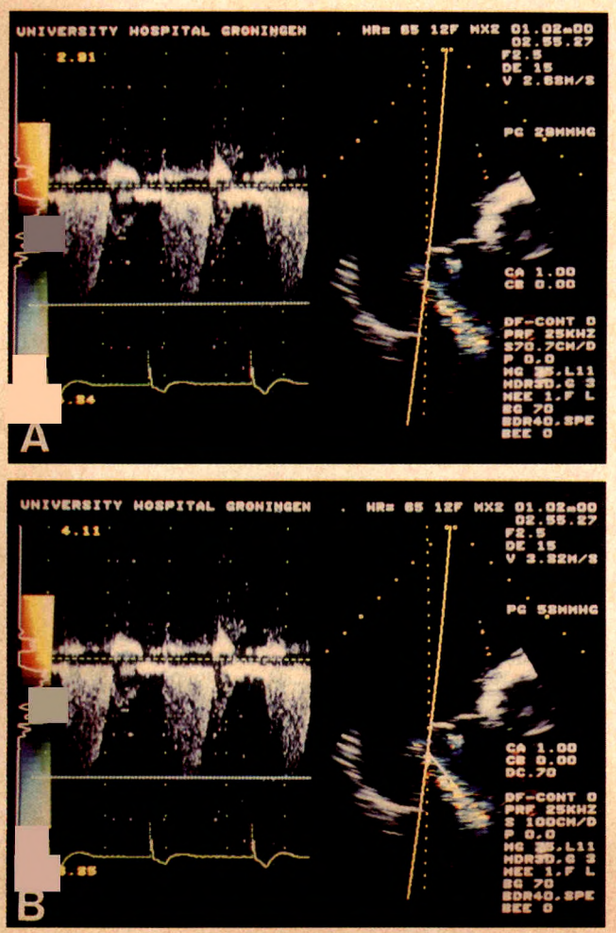
Noninvasive Measurement of Right Ventricular Systolic Pressure by Combined Color-Coded and Continuous-Wave Doppler Ultrasound

HANS P.M. HAMER, MD, PhD
BERT L. TAKENS, MD
JAN L. POSMA, MD
KONG I. LIE, MD, PhD

Noninvasive prediction of right ventricular (RV) pressure is a clinical challenge.[1-4] Doppler echocardiography is now routinely used to assess pulmonary hypertension.[5-10] Measurement of the flow velocity of tricuspid regurgitation is of great value in the evaluation of RV peak pressure. Without a pressure difference across the pulmonary valve, peak pressure in the pulmonary artery can be calculated from the flow velocity of the tricuspid regurgitation. Correlations with catheterization data are reasonably good, although in most studies extreme values are included in the calculations and this may result in unrealistically good correlations with catheterization data. Without visualization of the direction of the tricuspid regurgitation, underestimation of RV peak pressure can be expected in a number of patients because the direction of the tricuspid regurgitation flow is not necessarily the same as the Doppler sound beam. One still needs to search and listen for audio Doppler signals to record the measured maximal velocity. We undertook this study, therefore, attempting to answer the following questions: (1) Can continuous-wave (CW) Doppler alone accurately pre-



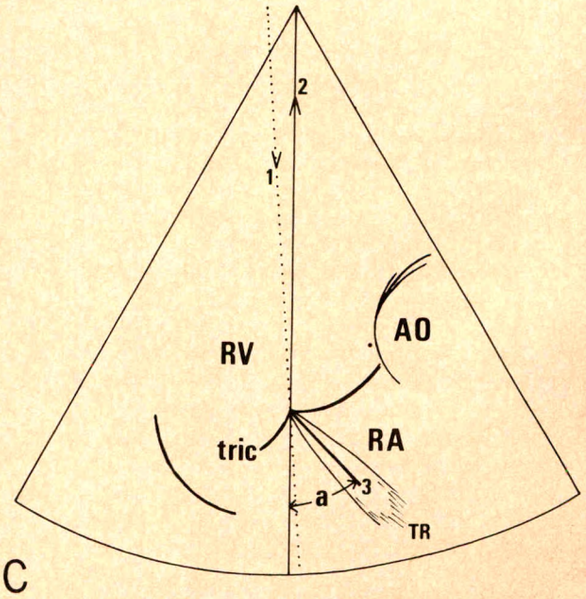


FIGURE 1. CC and CW Doppler echocardiograms without angle correction (*A*, peak pressure 29 mm Hg) and with angle correction (*B*, peak pressure 58 mm Hg), showing the method of establishing the angle between directions of CW sound beam and CC Doppler flow jet (*C*). a = angle; AO = aorta; RA = right atrium; RV = right ventricle; TR = visualized tricuspid regurgitation; tric = tricuspid valve; 1 = CW Doppler sound beam; 2 = direction of the receiving CW signal; 3 = line with which the angle is established.

From the Department of Cardiology, University Hospital Groningen, Groningen, The Netherlands. Manuscript received July 13, 1987; revised manuscript received October 10, 1987, and accepted October 25.

dict the RV peak pressure and what would be the correlation between Doppler and catheterization data in that most interesting group of patients, those with moderately elevated RV peak pressures? (2) Is the angle between the visualized tricuspid regurgitation with color-coded (CC) Doppler and the CW beam of importance for accurate measurement of the RV peak pressure? (3) In what percentage of patients can pulmonary hypertension be suspected by auscultation or phonocardiography?

CW and CC Doppler ultrasound examinations were performed in 51 patients undergoing right-sided heart catheterization. The group consisted of patients who consecutively underwent diagnostic catheterization for left-sided heart disease or for electrophysiologic investigations. The patients were clinically stable and had no change in therapy during several days before measurements. Doppler examinations were done 3 hours before catheterization. The group consisted of 31 men and 20 women, ages 19 to 73 years (54 ± 15). Sinus rhythm was present in 48 patients, 2 had a pacemaker rhythm and 1 had atrial fibrillation. On the basis of RV pressures at catheterization, patients were divided into 2 groups. Group 1 consisted of 16 patients with RV pressures <35 mm Hg and group 2 consisted of 35 patients with RV pressures ≥35 mm Hg.

Auscultation was performed with the patients supine, paying special attention to the loudness of the pulmonic closure sound and to the presence of a tricuspid regurgitation murmur. Phonocardiograms were made at the fourth rib at the left and right side of the sternum with cutoff frequencies of 35, 70, 140 and 240 Hz, together with a carotid pulse recording for definition of the pulmonic closure sound.

Doppler examinations were performed with a commercially available phased array echocardiograph with CC and CW Doppler (Toshiba 65A). A 2.5-MHz transducer was used for all studies. The patients lay in left lateral position. To find the best position for visualization of the tricuspid regurgitation, the parasternal, apical and subxyphoidal positions were investigated. The CC Doppler flow jet had to originate from the valve itself. This point was positioned in the middle of the sector image (Figure 1). The transducer was then turned around its long axis to obtain the largest angle and exclude the error created when the color flow jet has an angle in respect to the sector plane. The CW Doppler sound beam was arranged through the point of the tricuspid valve where the leakage was seen. The receiving Doppler signal line was positioned through the same point. From the best CW signal, also obtained by listening for the audio signals, maximal velocity was measured and pressure difference across the tricuspid valve calculated by means of the simplified Bernoulli equation $p = 4v^2$. The angle between CW and CC flow jet directions was established by positioning a line through the CC flow jet. This line originated form the crosspoint of both CW lines. The machine calculated the angle and corrected the CW measurement for it by using v-corrected = v-uncorrected/cos α. The peak transtricuspid pressure difference was judged to be the same as the RV peak pressure: in case of a slight tricuspid regurgitation the early

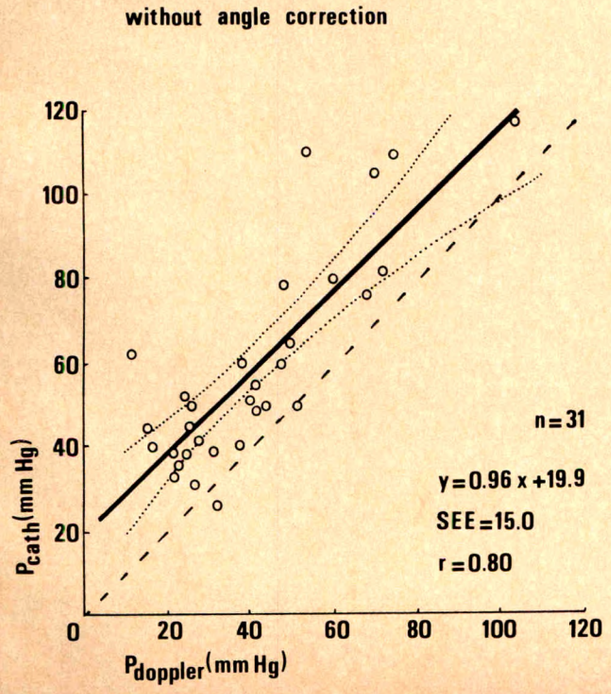

FIGURE 2. Correlation between measurements of RV peak pressures with CW Doppler and with catheterization for the 31 patients with visible and measurable tricuspid regurgitation without angle correction. The correlation is r = 0.80 (p <0.001).

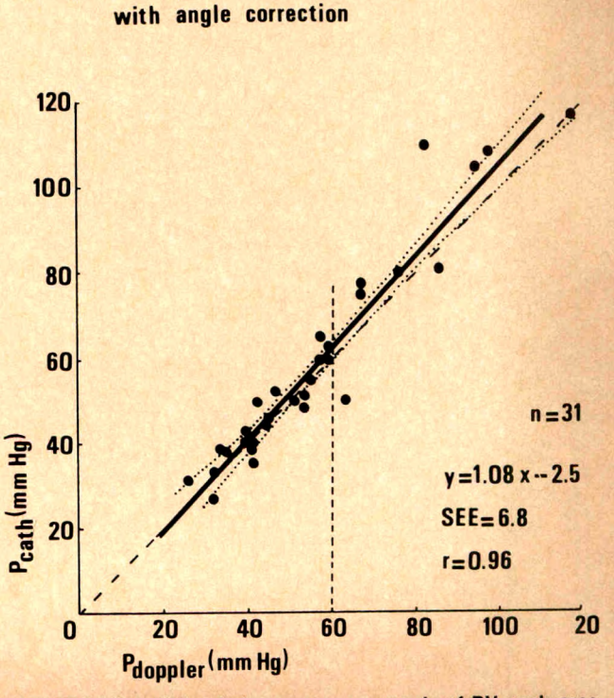

FIGURE 3. Correlation between measurements of RV peak pressures with CW Doppler and with catheterization for the 31 patients with visible and measurable tricuspid regurgitation with angle correction. The correlation is r = 0.96 (p <0.001).

systolic right atrial pressure is much lower than the mean right atrial pressure.

Doppler measurements were made by 2 investigators in separate sessions without knowledge of their results and of the results of catheterization measurements. Ten beats were analyzed in case of a sinus rhythm and at least 25 beats in case of atrial fibrillation. Measurements were made during end-expiratory periods. During catheterization, pressures in RV and pulmonary artery were measured at end-expiration. The patients did not have premedication.

The data are expressed as mean ± standard deviation. Linear regression analysis was used to assess the correlation between Doppler and catheterization RV pressures. Comparisons among groups were made with the unpaired Student t test and chi-square for nonpaired data and the McNemar test for paired data.

A pressure difference between RV and pulmonary artery was not found in any of the patients. For the 16 patients in group 1 the mean peak RV pressure was 27 ± 5 mm Hg (range 16 to 33); for the 35 patients in group 2 it was 58 ± 23 mm Hg (range 36 to 118).

Tricuspid regurgitation could be visualized with CC and also be measured with CW in 3 patients (19%) in group 1 and in 28 patients (80%) in group 2 ($p < 0.001$). For 17 patients in group 2 the transducer position was in the short axis of the aorta, for 9 patients it was at the apex and for 2 the location was subxyphoidal. An angle of <20° was found in 3 patients, 20 to 39° in 17 and ≥40° in 8.

For the 3 patients in group 1 and the 28 in group 2, the correlations between Doppler and catheterization measurements, with and without angle correction, are presented in Figures 2 and 3. By excluding extreme values (angle-corrected values >60 mm Hg), 22 of the 31 patients continued participating. All the excluded patients had RV pressures ≥50 mm Hg at catheterization. Without angle correction, a poor correlation was found for this important group of patients with moderately elevated RV peak pressures. However, the correlation was good with angle correction (Figures 4 and 5).

Without angle correction (CW alone), elevated RV pressures were detected in only 16 out of 28 patients in group 2 (sensitivity = 46%). With angle correction, 27 of the 28 patients were detected (sensitivity = 77%), a significant improvement over the results without angle correction ($p < 0.005$).

For smaller angles (<30°) the correlation was r = 0.94 after correcting for pressure differences (which remained good for larger angles, with r = 0.93).

At auscultation, 4 patients (11%) had a tricuspid regurgitation murmur. Patients with mitral regurgitation were excluded. A loud pulmonic closure sound (louder than the aortic closure sound at the fourth rib) was heard in 9 patients (26%). At phonocardiography, 12 patients (34%) had evidence of pulmonary hypertension according to the loudness of the pulmonic closure sound. There was no correlation between the magnitude of the pulmonary artery pressure and the splitting of the second heart sound.

The advantage of CC Doppler is that the angle between the CW Doppler sound beam and the direction of the tricuspid regurgitation can be visualized and the measurements corrected for this angle. The results of this study indicate that angle correction is important for calculating RV peak pressures and thus, in the

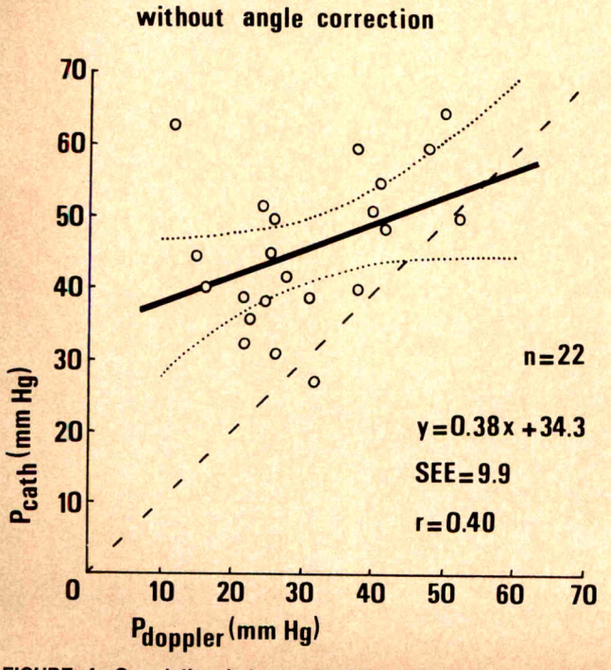

FIGURE 4. Correlation between angle-uncorrected Doppler RV peak pressures and catheterization measurements for the 22 patients with Doppler pressures ≤60 mm Hg. The correlation is r = 0.40 (not significant).

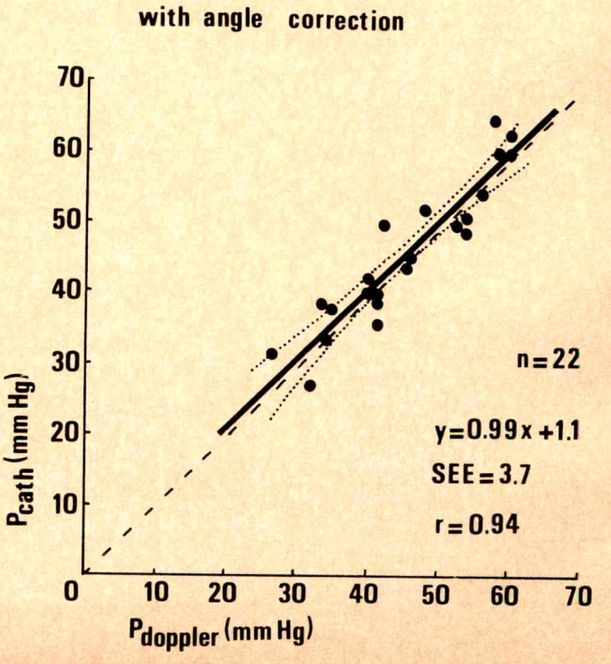

FIGURE 5. Correlation between angle-corrected Doppler RV peak pressures and catheterization measurements for the 22 patients with Doppler pressures ≤60 mm Hg. The correlation is r = 0.94 ($p < 0.001$).

absence of a pressure difference across the pulmonic valve, for pressures in the pulmonary artery.

The angles we found were rather large, but good correlations were found for even larger angles. Measurements were highly reproducible: interobserver variability was low and with a discrepancy of 1.8 ± 2.2 mm Hg.

In elevated RV peak pressures, tricuspid regurgitation could be found in 32 of 35 patients with CC or CW, or both. In 7 patients there was only a CC signal, or only a CW signal, or the angle could not be established. In such patients, pulsed Doppler measurements in the pulmonary artery can be helpful in determining the pressure in the pulmonary artery. Both angle visualization and CW measurement were possible in 28 of 35 patients (80%), which is about the same percentage found in the literature for CW measurements alone. Without angle correction only 57% of the patiens (16 of 28) were recognized with elevated pressures, whereas with angle correction this figure was 96% (27 of 28), which makes angle correction clinically important.

Combined CC and CW Doppler echocardiography provides a rather simple, very accurate and highly reproducible method for calculation of the peak RV pressure and thus—in the absence of pulmonic stenosis—the peak pressure in the pulmonary artery. The method gives excellent results and is a very important tool for use in patients with mild pulmonary hypertension. For this particular group of patients, the addition of color Doppler has proven to be valuable.

The AJC in March 1963

WILLIAM C. ROBERTS, MD

The AJC in March 1963 contained 21 articles occupying 140 pages, including 1 editorial, 11 major studies, 3 experimental (nonhuman) studies and 6 case reports. This piece will comment on 5 articles.

In a superb editorial entitled "Diet and atherosclerosis: truth and fiction" Snapper[1] from Brooklyn, New York, logically showed the detrimental influence of cholesterol intake and the lowering effect of polyunsaturated fatty acids on the serum total cholesterol level. He pointed out areas of the world where atherosclerosis is rare and cholelithiasis and phlebothrombosis "hardly ever occur." He stated that ". . . a diet devoid of cholesterol but rich in polyunsaturated acid prevents the *deposition* of cholesterol within the intima of arteries . . . . A diet with a high proportion of polyunsaturated fatty acids, begun in early childhood as a life-long regimen, will *prevent* the development of atherosclerosis, thrombosis and cholelithiasis."

Shubin and Weil[2] from Los Angeles, California, measured serum glutamic oxalacetic transaminase (SGOT), serum glutamic pyruvic transaminase (SGPT) and lactic dehydrogenase (LD) in 43 patients with shock caused by noncardiac conditions (hemorrhage, infection, neurologic injury and vascular obstruction). They found these levels to be elevated in 70%, 37% and 52%, respectively, indicating that elevations of these enzymes are not helpful in differentiating shock secondary to acute myocardial infarction from that caused by noncardiac conditions. Klein and Palmer[3] from San Diego, California, found a much higher elevation of SGOT and LD in patients with acute myocardial infarction associated with shock than in patients with uncomplicated acute myocardial infarction.

Greenwood and associates[4] from Toronto, Canada, analyzed results of closed mitral commissuratomy in 88 patients operated on by W.G. Bigelow between March 1951 and June 1953 and compared his results with those of 172 patients with mitral stenosis without operation but with a similar follow-up period. They concluded that mitral commissurotomy prolonged life, improved funtional capacity, prevented recurrence of hemoptysis (as long as the obstruction remained relieved) and reduced both the occurrence and recurrence of systemic embolism. If calcific deposits had been present in the stenotic valve, however, the 5-year results of commissurotomy were poor, with only 1 in 4 patients being improved over 5 years.

Samet and associates[5] from Miami Beach, Florida, using a "cardiac catheter electrode pacemaker" inserted in an antecubital vein and passed to the right ventricular outflow tract, treated 4 patients with complete heart block complicating acute myocardial infarction. Dramatic clinical improvement resulted from catheter-electrode pacemaking in all 4 patients.

The AJC in 1987

The year 1987 was a good one for the AJC. A total of 2,833 pages for articles (2,810 pages) and letters (23 pages) was published in the 16 regular issues of the AJC in 1987 (Table I). This number represents an increase of 189 pages (7%) for articles and letters compared to 1986. In addition to these 2,833 pages, 395 other editorial (i.e., nonadvertising) pages were published in the regular issues in 1987. Of this number, 202 were used for the "contents with abstracts," and I am pleased to report that the publisher is considering discontinuing this section in July 1988. The publisher also will change the layout of the "contents in brief" in July 1988.

The number of articles published in the regular issues in 1987 was 695, an average of 58 each month, and an increase of 79 articles (11%) compared to 1986 (Table I). Each of the 695 articles averaged 4.04 pages in length, a 5% decrease in average article length compared to the preceding year. Although the percent of articles in each of the various categories in 1987 was roughly similar to what it had been in 1986, the number of articles on systemic hypertension increased to 28 from 10 in the preceding year (Table I). Because systemic hypertension is such a common condition (60 million Americans have it), articles on this subject should, in my view, occupy more than 4% of the articles published. No experimental articles were published in 1987 (except those which could fit into the Brief Report format).

I am enormously pleased about how the *Brief Reports* section of the AJC has developed during the past 5.5 years. This section was initiated in September 1982. In 1983, 65 (80%) of the 81 brief reports published were single-case studies (Table II); in 1984, 122 (60%) of the 204 brief reports published were single-case studies; in 1985, 54% were single-case studies and in 1987 only 34% of the 203 brief reports published were single-case studies. In 1987, 33% of the brief reports involved >10 patients and many involved >100 patients. It is clear that the Brief Reports section of the *Journal* is no longer a case-report section. To emphasize this change, beginning in April 1988 the reports which include case descriptions will be placed in a new section to be called simply *Case Reports*. The Brief

TABLE I Number of Pages and Types of Articles Published in the Regular Issues of the AJC in 1983 to 1986

	1983	1984	1985	1986	1987

Reports will be reserved for major studies that are concise and have only 1 or 2 major points. At least a third of the articles published as Brief Reports were initially submitted as regular length articles but converted to the shorter format. I urge the readership to examine the brief reports more carefully because these reports provide the most information per page of any section in the *Journal*. The topics of the Brief Reports in 1987 were roughly similar to what they had been in 1986 (Table III). The editor particularly welcomes reader reaction to the Brief Reports.

And 1987 also was a good year for supplements. A total of 19 supplements was published in the AJC, and they included 279 articles occupying 1,576 pages (Table IV). Some of the more prominent cardiovascular investigators in the world served as guest editors of these supplements. The average interval between the symposium meeting and the publication of the proceedings of the symposium was 12 months. Supplements are published, however, within 3 months of receipt of all the manuscripts by the editor.

Thus, including both regular issues and supplements a total of 974 articles occupying 4,412 pages was published in the AJC in 1987. At a yearly subscription cost of $66.00, each article in 1987 cost a subscriber <7 pennies and each page for articles and letters, <2 pennies. The subscription cost throughout 1988 will remain the same as in 1987, so the *Journal* in 1988 should be an even better bargain.

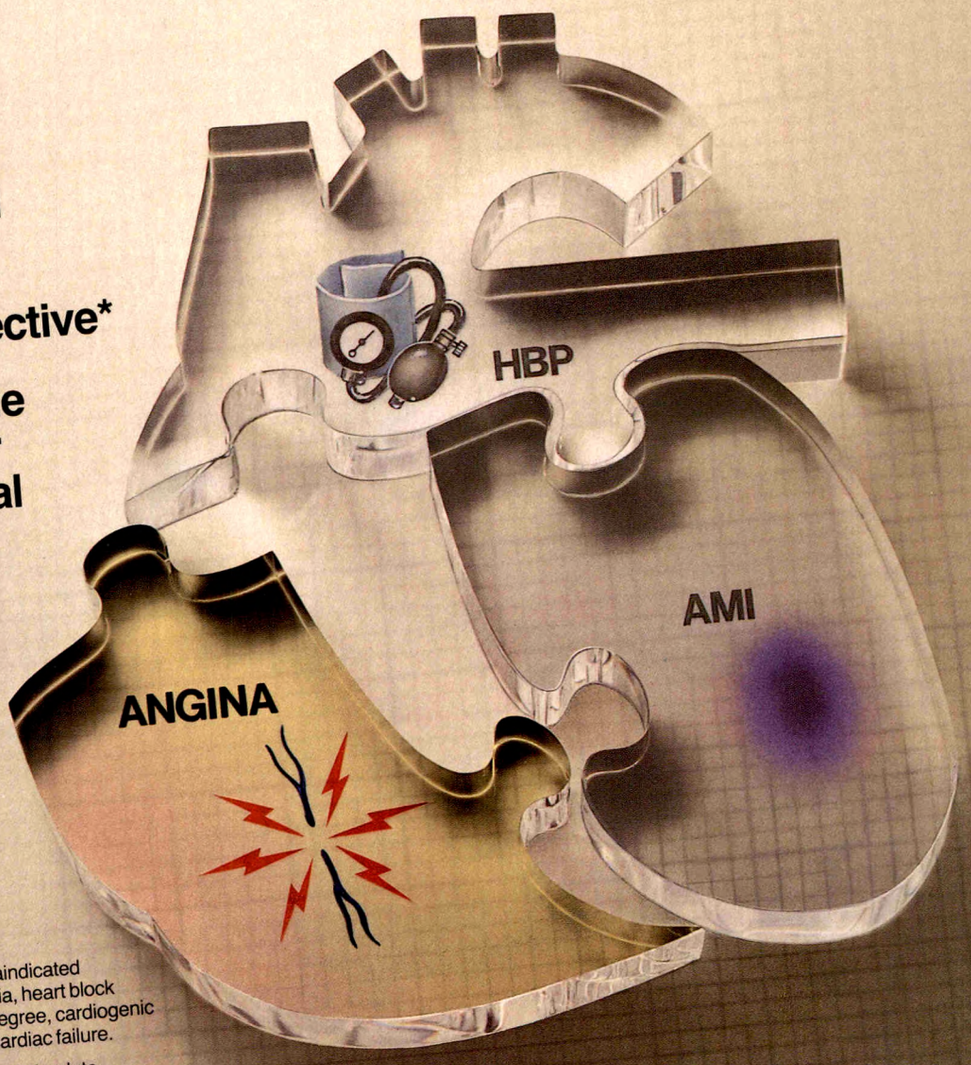
Editor-in-Chief

Lopressor® for ANGINA

Completes the picture of cardiovascular protection

- Reduces myocardial ischemia
- Cardioselective*
- Compatible with other antianginal therapies



Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure.

*Exerts a relative, not absolute, preference for beta-one receptors.

Please consult Brief Summary of Prescribing Information on next page.

Lopressor®
metoprolol tartrate

Changing the Course of Cardiovascular Care

Tablets
Ampuls
Prefilled Syringes

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

CONTRAINDICATIONS
Hypertension and Angina
Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **WARNINGS**).
Myocardial Infarction
Lopressor is contraindicated in patients with a heart rate < 45 beats/min; second- and third-degree heart block; significant first-degree heart block (P-R interval ≥ 0.24 sec); systolic blood pressure < 100 mmHg; or moderate-to-severe cardiac failure (see **WARNINGS**).

WARNINGS
Hypertension and Angina
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive and angina patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and Lopressor slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic. The response should be observed closely. If cardiac failure continues, despite adequate digitalization and diuretic therapy, Lopressor should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have occurred. When discontinuing chronically administered Lopressor, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of 1-2 weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Lopressor administration should be reinstated promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Lopressor therapy abruptly even in patients treated only for hypertension.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly, and the lowest possible dose of Lopressor should be used. In these circumstances it would be prudent initially to administer Lopressor in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See DOSAGE AND ADMINISTRATION.)**

Major Surgery: The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial; the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Lopressor, like other beta blockers, is a competitive inhibitor of beta-receptor agonists, and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes and Hypoglycemia: Lopressor should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade, which might precipitate a thyroid storm.

Myocardial Infarction
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function, and beta blockade carries the potential hazard of depressing myocardial contractility and precipitating or exacerbating minimal cardiac failure.

During treatment with Lopressor, the hemodynamic status of the patient should be carefully monitored. If heart failure occurs or persists despite appropriate treatment, Lopressor should be discontinued.

Bradycardia: Lopressor produces a decrease in sinus heart rate in most patients; this decrease is greatest among patients with high initial heart rates and least among patients with low initial heart rates. Acute myocardial infarction (particularly inferior infarction) may in itself produce significant lowering of the sinus rate. If the sinus rate decreases to < 40 beats/min, particularly if associated with evidence of lowered cardiac output, atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, Lopressor should be discontinued, and cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

AV Block: Lopressor slows AV conduction and may produce significant first- (P-R interval ≥0.26 sec), second-, or third-degree heart block. Acute myocardial infarction also produces heart block.

If heart block occurs, Lopressor should be discontinued and atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

Hypotension: If hypotension (systolic blood pressure ≤ 90 mmHg) occurs, Lopressor should be discontinued, and the hemodynamic status of the patient and the extent of myocardial damage carefully assessed. Invasive monitoring of central venous, pulmonary capillary wedge, and arterial pressures may be required. Appropriate therapy with fluids, positive inotropic agents, balloon counterpulsation, or other treatment modalities should be instituted. If hypotension is associated with sinus bradycardia or AV block, treatment should be directed at reversing these (see above).

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, Lopressor may be used with extreme caution in patients with bronchospastic disease. Because it is unknown to what extent beta$_2$-stimulating agents may exacerbate myocardial ischemia and the extent of infarction, these agents should *not* be used prophylactically. If bronchospasm not related to congestive heart failure occurs, Lopressor should be discontinued. A theophylline derivative or a beta$_2$ agonist may be administered cautiously, depending on the clinical condition of the patient. Both theophylline derivatives and beta$_2$ agonists may produce serious cardiac arrhythmias.**

PRECAUTIONS
General
Lopressor should be used with caution in patients with impaired hepatic function.
Information for Patients
Patients should be advised to take Lopressor regularly and continuously, as directed, with or immediately following meals. If a dose should be missed, the patient should take only the next scheduled dose (without doubling it). Patients should not discontinue Lopressor without consulting the physician.

Patients should be advised (1) to avoid operating automobiles and machinery or engaging in other tasks requiring alertness until the patient's response to therapy with Lopressor has been determined; (2) to contact the physician if any difficulty in breathing occurs; (3) to inform the physician or dentist before any type of surgery that he or she is taking Lopressor.
Laboratory Tests
Clinical laboratory findings may include elevated levels of serum transaminase, alkaline phosphatase, and lactate dehydrogenase.
Drug Interactions
Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension or marked bradycardia, which may produce vertigo, syncope, or postural hypotension.
Carcinogenesis, Mutagenesis, Impairment of Fertility
Long-term studies in animals have been conducted to evaluate carcinogenic potential. In 2-year studies in rats at three oral dosage levels of up to 800 mg/kg per day, there was no increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes that appeared to be drug related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in Swiss albino mice at three oral dosage levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant or total (benign plus malignant) lung tumors, nor in the overall incidence of tumors or malignant tumors. This 21-month study was repeated in CD-1 mice, and no statistically or biologically significant differences were observed between treated and control mice of either sex for any type of tumor.

All mutagenicity tests performed (a dominant lethal study in mice, chromosome studies in somatic cells, a Salmonella/mammalian-microsome mutagenicity test, and a nucleus anomaly test in somatic interphase nuclei) were negative.

No evidence of impaired fertility due to Lopressor was observed in a study performed in rats at doses up to 55.5 times the maximum daily human dose of 450 mg.
Pregnancy Category C
Lopressor has been shown to increase postimplantation loss and decrease neonatal survival in rats at doses up to 55.5 times the maximum daily human dose of 450 mg. Distribution studies in mice confirm exposure of the fetus when Lopressor is administered to the pregnant animal. These studies have revealed no evidence of impaired fertility or teratogenicity. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers
Lopressor is excreted in breast milk in very small quantity. An infant consuming 1 liter of breast milk daily would receive a dose of less than 1 mg of the drug. Caution should be exercised when Lopressor is administered to a nursing woman.
Pediatric Use
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
Hypertension and Angina
Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression has been reported in about 5 of 100 patients. Mental confusion and short-term memory loss have been reported. Headache, nightmares, and insomnia have also been reported.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations; congestive heart failure; peripheral edema; and hypotension have been reported in about 1 of 100 patients. (See **CONTRAINDICATIONS, WARNINGS,** and **PRECAUTIONS**.)

Respiratory: Wheezing (bronchospasm) and dyspnea have been reported in about 1 of 100 patients (see **WARNINGS**).

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, dry mouth, gastric pain, constipation, flatulence, and heartburn have been reported in about 1 of 100 patients.

Hypersensitive Reactions: Pruritus or rash have occurred in about 5 of 100 patients. Worsening of psoriasis has also been reported.

Miscellaneous: Peyronie's disease has been reported in fewer than 1 of 100,000 patients. Musculoskeletal pain, blurred vision, and tinnitus have also been reported.

There have been rare reports of reversible alopecia, agranulocytosis, and dry eyes. Discontinuation of the drug should be considered if any such reaction is not otherwise explicable.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor.
Myocardial Infarction
Central Nervous System: Tiredness has been reported in about 1 of 100 patients. Vertigo, sleep disturbances, hallucinations, headache, dizziness, visual disturbances, confusion, and reduced libido have also been reported, but a drug relationship is not clear.

Cardiovascular: In the randomized comparison of Lopressor and placebo described in the **CLINICAL PHARMACOLOGY** section, the following adverse reactions were reported:

	Lopressor	*Placebo*
Hypotension (systolic BP < 90 mmHg)	27.4%	23.2%
Bradycardia (heart rate < 40 beats/min)	15.9%	6.7%
Second- or third-degree heart block	4.7%	4.7%
First-degree heart block (P-R ≥ 0.26 sec)	5.3%	1.9%
Heart failure	27.5%	29.6%

Respiratory: Dyspnea of pulmonary origin has been reported in fewer than 1 of 100 patients.

Gastrointestinal: Nausea and abdominal pain have been reported in fewer than 1 of 100 patients.

Dermatologic: Rash and worsened psoriasis have been reported, but a drug relationship is not clear.

Miscellaneous: Unstable diabetes and claudication have been reported, but a drug relationship is not clear.
Potential Adverse Reactions
A variety of adverse reactions not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse reactions to Lopressor.

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **CONTRAINDICATIONS**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Hypersensitive Reactions: Fever combined with aching and sore throat, laryngospasm, and respiratory distress.

OVERDOSAGE
Acute Toxicity
Several cases of overdosage have been reported, some leading to death.

Oral LD_{50}'s (mg/kg): mice, 1158-2460; rats, 3090-4670.
Signs and Symptoms
Potential signs and symptoms associated with overdosage with Lopressor are bradycardia, hypotension, bronchospasm, and cardiac failure.
Treatment
There is no specific antidote.

In general, patients with acute or recent myocardial infarction may be more hemodynamically unstable than other patients and should be treated accordingly (see **WARNINGS, Myocardial Infarction**).

On the basis of the pharmacologic actions of Lopressor, the following general measures should be employed:

Elimination of the Drug: Gastric lavage should be performed.

Bradycardia: Atropine should be administered. If there is no response to vagal blockade, isoproterenol should be administered cautiously.

Hypotension: A vasopressor should be administered, e.g., levarterenol or dopamine.

Bronchospasm: A beta$_2$-stimulating agent and/or a theophylline derivative should be administered.

Cardiac Failure: A digitalis glycoside and diuretic should be administered. In shock resulting from inadequate cardiac contractility, administration of dobutamine, isoproterenol, or glucagon may be considered.

SPASM OF SAPHENOUS VEINS USED AS CONDUITS FOR AORTOCORONARY BYPASS GRAFTING

I read the brief report by Mann and associates on morphologic documentation of spasm of a saphenous vein used as a coronary conduit.[1] The statement was made that spasm of a saphenous vein used as an aortocoronary conduit had not been reported. In actuality, at least 4 reports of documented spasm in an aortocoronary saphenous vein graft have appeared.[2-5] Yours was a most interesting case in that it had autopsy demonstration of persistent spasm.

GERALD M. LAWRIE, MD
Houston, Texas
30 April 1987

In the article by Mann et al[1] regarding aortocoronary vein graft spasm, the assertion is made that "Spasm of saphenous veins used as aortocoronary conduits has not been reported." This is incorrect. It is, however, the first case in which the diagnosis has been at autopsy. The first report of spasm occurring in an aortocoronary vein graft was by Victor et al.[2] A commentary by Heupler[6] accompanied the article. In that commentary, Heupler reported another case of vein graft spasm that had been observed during surgery at the Cleveland Clinic. I presented 2 such cases at the meeting of the Section on Cardiovascular Surgery at the 49th Annual Scientific Assembly of the American College of Chest Physicians in October 1983. My second case was serendipitously recorded on video tape in the operating room. The video tape clearly showed the area of spasm and its dramatic response to treatment. The case described by Victor et al documented angiographically the existence of the spasm and its successful treatment. In each one of these cases (except for that described by Mann et al) the patients survived as a result of prompt recognition of the problem and treatment by direct intracoronary nitroglycerin infusion either in the catheterization laboratory or in the operating room.

As I stated in my presentation at the American College of Chest Physicians and as Heupler pointed out in his commentary, vein graft spasm should be considered in any patient with aortocoronary vein grafts who experiences sudden deterioration in hemodynamics associated with signs of acute ischemia. Confirmation of diagnosis and treatment can be accomplished either by direct observation in the operating room or by angiographic evaluation, and treatment with intracoronary nitroglycerin infusion should be started immediately.

THOMAS J. BERGER, MD
Great Falls, Montana
5 May 1987

REPLY: We thank Drs. Lawrie and Berger for their good letters. They are right. We examined the 5 articles[2-6] brought to our attention and certain data in the 6 patients described in them are summarized in Table I. Coronary angiography was prompted after coronary artery bypass grafting (CABG) in 4 of the 6 patients because of recurrence of angina pectoris. In these 4 patients, the interval from CABG to postoperative coronary angiography ranged from 60 to 180 days (mean 139). The other 2 patients had no recurrence of symptoms after CABG, but had coronary angiography, nevertheless, 7 and 990 days after CABG. In 5 patients, spasm of a saphenous vein used as an aortocoronary bypass conduit occurred during the coronary angiographic procedure when the catheter tip was located in the *saphenous vein*. In the remaining patient, however, spasm of the saphenous vein occurred in the operating room after both anastomoses had been done, and it disappeared with papaverine infusion into the graft. The degree of diameter reduction of the lumen of the saphenous vein by the spasm was severe, ranging from 50 to 100% (mean 86). The spasm of the saphenous vein (to native right in 3 patients, to native left anterior descending in 1 and to native left obtuse marginal coronary artery in 1) was associated with electrocardiographic ST-segment elevation in 2 patients, both of whom also had angina. We are surprised by the occurrence of spasm in a saphenous vein used as an aortocoronary conduit this long (≥135 days in 4 of the 6 patients) after CABG because by this time the wall of the saphenous vein has lost most of its smooth muscle cells and is more of a fibrous tube than a muscular tube.[7]

Again, we thank Drs. Lawrie and Berger for their "sharp eyes." Our own case, however, was the first in whom spasm of a saphenous vein used as a coronary conduit was demonstrated anatomically.

TABLE I Clinical Data in 6 Reported Patients with Angiographically or Surgically Demonstrated Spasm of a Saphenous Vein Used as a Coronary Conduit After Aortocoronary Bypass Grafting

Case	First Author (Year)	Age (yr), Sex	Previous CA Spasm	Interval (days) CABG → C	Symptom Prompting C	Catheter in SV at Time of SV Spasm (Native CA with SV)	AP During SV Spasm	ST ↑ During SV Spasm	Percent Diameter Narrowing of SV by Spasm
1	Baduini (1981)	49, M	0	135	AP	+(R)	+	+	100
2	Victor (1981)	66, M	0	60	AP	+(LOM)	−	0	90
3	Heupler (1981)	− −	−	7	0	0	−	−	>75
4	Walinsky (1982)	66, F	+	180	AP	+(R)	+	+	100
5	Heijman (1983)	52, M	0	180	AP	+(LAD)	0	0	50
6		54, M	0	990	0	+(R)	0	0	90

AP = angina pectoris; C = catheterization; CA = coronary artery; CABG = coronary artery bypass grafting; LAD = left anterior descending; LOM = left obtuse marginal; R = right; SV = saphenous vein; + = positive or present; 0 = negative or absent; − no information available.

Instructions to Authors

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY, that upon submission, they become the property of the Publisher, that the work has not been previously published, and that the data in the manuscript have been reviewed by all authors, who agree with the analysis of the data and the conclusions reached in the manuscript. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced without the written permission of the Publisher. Statements in articles are the responsibility of the authors.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 7960 Old Georgetown Road, Suite 2C, Bethesda, Maryland 20814. Please include the corresponding author's phone number. The covering letter should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make (for example, the elimination of 1 or more figures or tables or a portion of the text) to increase the likelihood of publication of their work in the *Journal.* Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The names of investigators considered unlikely by the authors to give nonbiased reviews of their work also may be submitted, and this request is honored.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript including text, references, figures, legends and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page, which should include the title, the full names and academic degrees of the authors, and the institution and city and state or city and country from which the work originated; (2) second title page, with only the title of the article (page not numbered); (3) abstract; (4) text; (5) acknowledgment; (6) references; (7) figure legends; (8) miniabstract for Table of Contents that includes the full title and names (without academic degrees) of the authors (page not numbered); and (9) tables. Number the title page as 1, abstract page as 2, and so forth. (Leave the second title page and the miniabstract page unnumbered.) Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references) with at least 25-mm (1-inch) margins.

The second title page, on which the names and institutions of the authors are omitted, gives the Editor in Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be solicited. The authors should state which type of review they wish in the covering letter; this request is honored.

TITLE PAGE, TABLE OF CONTENTS, ABSTRACT AND MINIABSTRACT: For the **complete title page**, include the full first or middle and last names of all authors. Provide a short running title of 3 to 6 words. List the institution and address from which the work originated, and provide information about grant support if necessary. If the work described is supported by a grant from a pharmaceutical company, that fact should be stated on the title page. Add at the bottom the phrase, "Address for reprints:" followed by full name and address with zip code. Limit the **abstract** to 250 words and the Table of Contents **miniabstract** to 150 words. List 2 to 6 **key words** for subject indexing at the end of the abstract.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as the Methods, Results and Discussion. **Abbreviations** are permitted, but no more than 3 per manuscript, and then they must be used on every page of the manuscript after they are initially spelled out (followed by the abbreviation) in both abstract and introduction. Abbreviations are best limited to phrases in the article's title. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence, but try not to begin sentences with numbers. Use symbols for less than (<), greater than (>) and percent (%). Indent for paragraphs except the first one in both abstract and introduction. Consult the Uniform Requirements for Manuscripts Submitted to Biomedical Journals, published in *The Annals of Internal Medicine* June 1982;96:766–771, and also the *Stylebook/Editorial Manual of the American Medical Association.*

REFERENCES: List all authors, year, volume and inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts, but if they are used, indicate them as such by the abbreviation (abstr) after the title. Do not use periods after authors' initials or after abbreviations for titles of journals. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications, unpublished observations, and manuscripts submitted but not yet accepted for publication do not constitute references.

Journal: Harvey W, Heberden W, Withering W, Stokes W, Murrell W, Einthoven W, Osler W. Anomalies and curiosities of cardiology and of cardiologists. Reflections of famous medical Williams. Am J Cardiol 1984;53:900–915.

Chapter in Book: Cabot RC, White PD, Taussig HB, Levine SA, Wood P, Friedberg CK, Nadas AS, Hurst JW, Braunwald E. How to write cardiologic textbooks. In: Hope JA, ed. A Treatise on Disease of the Heart and Great Vessels. London: Yorke Medical Books, 1984;175–200.

Book: Carrel A, Cutler EC, Gross RE, Blalock A, Craffoord C, Brock RC, Bailey CP, DeBakey ME. The Closing of Holes, Replacing of Valves and Inserting of Pipes, or How Cardiovascular Surgeons Deal with Knives, Knaves and Knots. New York: Yorke University Press, 1984:903.

FIGURES: Submit 3 glossy unmounted prints of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all charts (line drawings). Make decimals, broken lines, and so on, clear enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by title of the article; omit the authors' names so that blinded reviews can be obtained. Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figures. Limit figures to the number necessary to present the message clearly. Type **figure legends** on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author.

TABLES: Place each table on a separate page, typed double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating numbers of patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate "positive" or "present", a zero (0) for "negative" or "absent," and dash (—) for "no information available" or "not done." Do not use "yes" or "no" or "more."

BRIEF REPORTS: Brief Reports must be limited to no more than 4 text pages (including the title page) and 6 references. Longer ones may be returned without review. Neither an abstract nor a Table of Contents miniabstract is required for a Brief Report. Subheadings are not used.

LETTERS (For Publication): The author who submits a letter for consideration for publication should provide a covering letter on his/her own stationery to the Editor in Chief stating why the letter should be published. The letter for consideration for publication should be typed, double-spaced, on a separate sheet of plain white paper and limited, with few exceptions, to 2 pages. The original and 2 xerographic copies should be submitted. A title for the letter should be provided at the top of the page. At the end of the letter, the writer's full name and city and state (or country if outside the United States) should be provided. The author's title and institution should not be included. The word "References" does not appear above the list of references in published letters. References should be double-spaced. A letter concerning a particular article in the *Journal* must be received (from authors within the United States) within 2 months of the article's publication.

REPRINTS: Price schedules and order cards for reprints are mailed to the author upon publication of the article. Individual reprints must be obtained through the author.

PERMISSIONS: Permission to reproduce figures published in the Journal is obtained by writing to: Managing Editor, THE AMERICAN JOURNAL OF CARDIOLOGY, 249 West 17th St., New York, NY 10011.

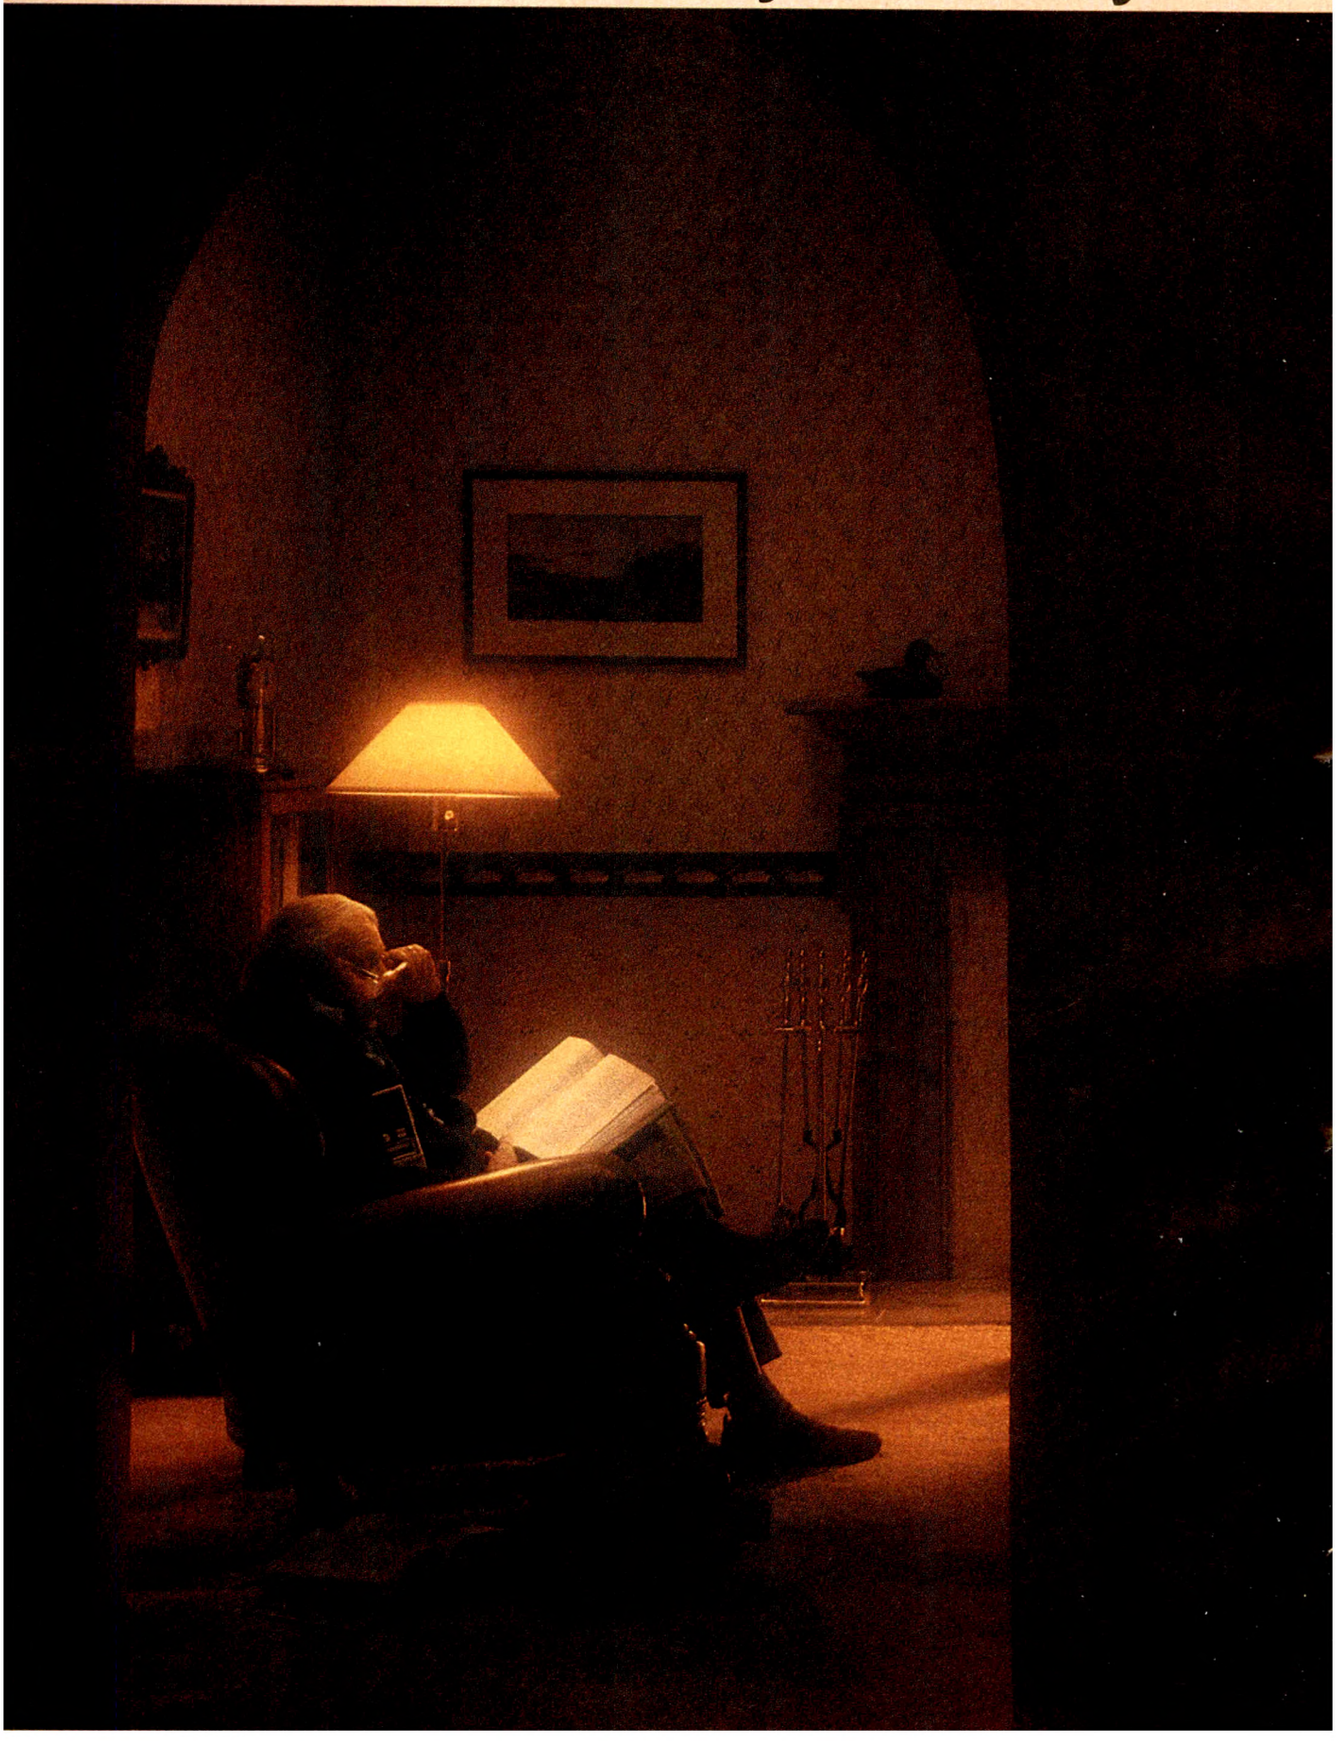
HP's ambulatory ECG system



also reads the fine print.

HP's new ambulatory ECG analyzer reads even subtle ECG changes in your patients, and can enhance your ability to identify abnormalities. With immediate high-fidelity signal processing, not available with tape systems, HP's solid-state analyzer reads every beat from both channels using techniques verified for accuracy according to AAMI standards. It's also compact, so it won't interfere with patient activities. In your office, the analyzer plugs into an HP personal computer and LaserJet printer for review and printing of reports. An efficient, complete system. But because it's PC-based, very affordable.

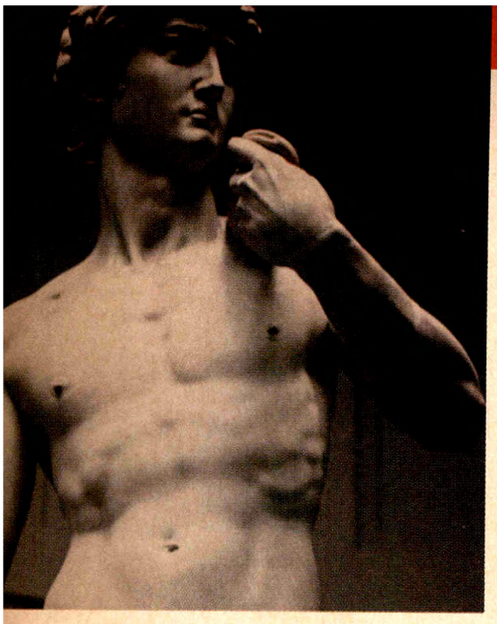
Ambulatory ECG. The comprehensive reader from Hewlett-Packard. For more information, write Hewlett-Packard Company, McMinnville Division, 1700 South Baker Street, McMinnville, OR 97128.

Please Visit Exhibit No. 2442 at ACC's 37th Scientific Session, March 28–31.

Full disclosure now available.

Advanced technology is just the beginning.

HEWLETT PACKARD



ENKAID®
(encainide HCl)

An alternative to classic antiarrhythmic therapy

For symptomatic non-sustained V-Tach and frequent PVCs

Treatment of symptomatic PVCs and non-sustained V-Tach should be reserved for patients in whom, in the opinion of the physician, the benefits of antiarrhythmic therapy outweigh the risks (e.g., proarrhythmia).

For documented life-threatening arrhythmias

Therapy should be initiated in the hospital for patients with sustained V-Tach and is also advisable for patients with a relatively high risk of proarrhythmia and at the time of a dose increase to 200 mg/day or above.

© 1988 Bristol-Myers U.S. Pharmaceutical and Nutritional Group

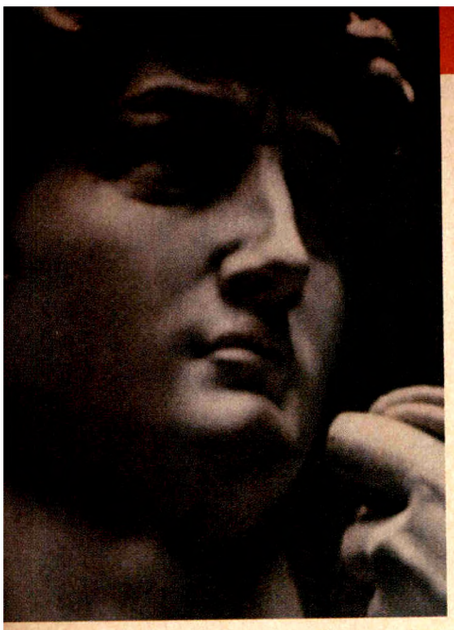
quinidine
Abolished non-sustained V-Tach in
47%
of patients
43%
had PVC suppression ≥90%[1]
39%[2]
of all patients had diarrhea
Randomized, double-blind crossover comparative clinical trial with quinidine utilizing 187 outpatients with ventricular arrhythmias who, in the opinion of the investigators, required therapy.



ENKAID®
(encainide HCl)

Effective with no changes in cardiac performance

- Studies of hemodynamic effects show no changes in:
  - left ventricular ejection fraction
  - cardiac or stroke volume index
  - pulmonary capillary wedge pressure
- Effective even in patients refractory to other antiarrhythmics.

ENKAID® (encainide HCl)

Dosage	Usual Recommendation
Initial dose	25 mg t.i.d.*
First increment (if required)	35 mg t.i.d.*
Second increment (if required)	50 mg t.i.d.*
Maximum recommended	50 mg q.i.d.**

*approximately q8h **approximately q6h

Initiate therapy at lowest dosage and increase gradually. Allow 3 to 5 days between dosing increments.

CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION

INDICATIONS AND USAGE
ENKAID is indicated for the treatment of documented life-threatening arrhythmias, such as sustained ventricular tachycardia.

ENKAID is also indicated for the treatment of patients with symptomatic non-sustained ventricular tachycardia and frequent premature ventricular complexes. Because of the proarrhythmic effects of ENKAID, its use in these less severe arrhythmias should be reserved for patients in whom, in the opinion of the physician, the benefits of treatment outweigh the risks.

For patients with sustained ventricular tachycardia, ENKAID, like other antiarrhythmics should be initiated in the hospital. Hospitalization is also advisable for other patients with a relatively high risk of proarrhythmia including patients with symptomatic congestive heart failure, cardiomyopathy or non-sustained ventricular tachycardia, depending on their cardiac status and underlying cardiac disease. Patients should also be hospitalized at the time of a dose increase to 200 mg per day or above (see **DOSAGE AND ADMINISTRATION**).

The effects of ENKAID in patients with a recent acute myocardial infarction and in patients with supraventricular arrhythmias have not been adequately studied.

As is the case for other antiarrhythmic agents, there is no evidence from controlled trials that the use of ENKAID favorably affects survival or the incidence of sudden death.

CONTRAINDICATIONS
ENKAID is contraindicated in patients with preexisting second- or third-degree AV block, or with right bundle branch block when associated with a left hemiblock (bifascicular block), unless a pacemaker is present to sustain the cardiac rhythm should complete heart block occur. ENKAID is also contraindicated in the presence of cardiogenic shock or known hypersensitivity to the drug.

WARNINGS
Proarrhythmia
ENKAID, like other antiarrhythmic agents, can cause new or worsened arrhythmias. Such proarrhythmic effects range from an increase in frequency of PVCs to the development of more severe ventricular tachycardia; e.g., tachycardia that is more sustained or more resistant to conversion to sinus rhythm, with potentially fatal consequences.

In patients with malignant arrhythmias, it is often difficult to distinguish a spontaneous variation in the patient's underlying rhythm disorder from drug induced worsening, so the following occurrence rates must be considered approximations.

Overall, in clinical trials with ENKAID about 10% of all patients had proarrhythmic events, about 6% of them representing new or worsened ventricular tachycardia. Provocation or aggravation occurred most frequently in patients who had a history of sustained ventricular tachycardia (12% of such patients), cardiomyopathy (16%), congestive heart failure (12%) or sustained ventricular tachycardia with cardiomyopathy or congestive heart failure (17%). The incidence of proarrhythmic events in patients without ventricular tachycardia or overt manifestations of clinical heart disease ranged from 3 to 4%. Proarrhythmia occurred least frequently in patients with no known structural heart disease. Age, sex, baseline ECG intervals, or ECG changes caused by ENKAID were not predictive of the occurrence of proarrhythmia.

A review of deaths in clinical trials indicates that about 1% of patients might have died of a possible proarrhythmic effect of ENKAID, virtually all of them patients with a history of ventricular tachycardia. In most cases patients had a history of sustained ventricular tachycardia or ventricular fibrillation.

Proarrhythmic events occurred most commonly during the first week of therapy and were much more common when doses exceeded 200 mg/day. Initiating therapy at 75 mg/day combined with gradual dose adjustment reduced the risk of proarrhythmia (See DOSAGE AND ADMINISTRATION).

Congestive Heart Failure
New or worsened congestive heart failure (CHF) attributed to ENKAID occurred infrequently (< 1%); nevertheless, ENKAID should be used cautiously in patients with CHF or congestive cardiomyopathy.

Electrolyte Disturbances
Hypokalemia or hyperkalemia may alter the effects of Class I antiarrhythmic drugs. Preexisting hypokalemia or hyperkalemia should be corrected before administration of ENKAID.

Sick Sinus Syndrome—(Bradycardia-Tachycardia Syndrome)
ENKAID should be used only with extreme caution in patients with sick sinus syndrome because it may cause sinus bradycardia, sinus pause, or sinus arrest.

Electrocardiographic Changes
ENKAID slows conduction and consequently produces dose related changes in the PR and QRS intervals. The intervals increase in a linear manner at doses from 30 to 225 mg/day. There is no consistent change in JT. The QTc interval is increased, but only to the extent of the increase in QRS interval.

Clinically significant changes in cardiac conduction have been observed. Sinus bradycardia, sinus pause, or sinus arrest occurred in 1% of the patients and prolongation of QRS interval to greater than/or equal to 0.20 sec developed in about 7% of the patients. The incidence of second- or third-degree AV block was less, 0.5% and 0.2% respectively.

Effects on Pacemaker Thresholds
The safety of ENKAID in patients with permanently implanted programmable pacemakers has been established in a small (10 patient) study which evaluated the effects of increasing doses on pacemaker thresholds. ENKAID has a limited potential for increasing pacemaker thresholds. Only one subject had a clinically significant change that would require pacemaker reprogramming and that occurred only at the highest dose tested (75 mg t.i.d.). These effects were reversed when the drug was discontinued. It is advisable to establish pacemaker threshold prior to encainide administration and at regular intervals during therapy. Reprogramming of multiprogrammable pacemakers may be required to increase voltage or pulse width. ENKAID should not be administered to patients with existing poor thresholds or non-programmable pacemakers unless suitable pacing rescue is available. In addition to possible rise in pacing threshold, ENKAID may suppress ventricular escape rhythms.

PRECAUTIONS
Drug Interactions
In prospective studies single and multiple doses of ENKAID have had no significant effect on serum digoxin levels. Likewise, combined digoxin/ENKAID therapy has been administered without adverse effects.

Experience has indicated no obvious problems with the combined use of ENKAID and other antiarrhythmic agents, diuretics, beta blockers or calcium channel blockers. However, because of possible additive pharmacologic effects, caution is indicated when ENKAID is used with another antiarrhythmic agent or any other drug that affects cardiac conduction.

Cimetidine (300 mg q.i.d.) increases plasma concentrations of encainide and its active metabolites. Although no clinically

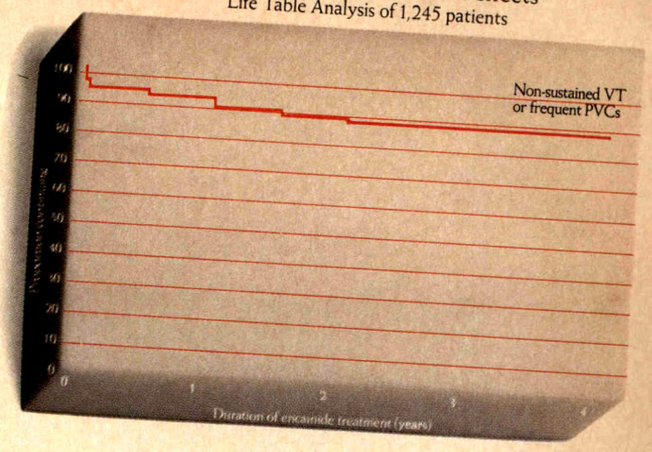
Well tolerated in long-term therapy

■ Few discontinuations due to side effects even after 4 years.

The most serious side effects of Enkaid are dizziness and blurred vision. In clinical studies with Enkaid, about 10% of patients had proarrhythmic events, occurring most frequently in patients with sustained ventricular tachycardia or underlying heart disease.

See brief summary for more information on Enkaid's side effects in life-threatening arrhythmias. Hospitalization is recommended in a facility with cardiac monitoring capabilities for patients with sustained V-Tach, sinus node dysfunction, cardiomyopathy and/or CHF, or at the time of a dose increase to 200 mg/day or above.

Discontinuations due to side effects[3]
Life Table Analysis of 1,245 patients



ENKAID® (encainide HCl)

An alternative to classic antiarrhythmic therapy

significant consequences have been reported, caution should be utilized when the two drugs are administered simultaneously. ENKAID dosage should be reduced if cimetidine is to be given to a patient taking ENKAID.

In vitro binding studies with several drugs that may be administered concomitantly have not revealed any significant alteration in the protein binding of encainide, ODE, or MODE; nor did high concentrations of encainide and its metabolites alter the binding of the other medications including such highly protein bound drugs as warfarin.

Hepatic Impairment

Patients with hepatic impairment have a significantly reduced rate of elimination of encainide, probably as a consequence of decreased metabolism to ODE and MODE; serum concentrations of ODE and MODE, however, are little altered. There is insufficient experience to be certain about the need for alterations in the dose and/or dosing interval of ENKAID in patients with hepatic disease, but it is prudent to increase doses cautiously.

Renal Impairment

Limited data suggest that reduction in the elimination of encainide and its active metabolites ODE and MODE in patients with severe renal impairment (serum creatinine >3.5 mg/dl or creatinine clearance of less than 20 ml/min) results in significant accumulation of metabolites and, to a lesser degree, encainide. In such patients therapy with ENKAID should be initiated with a single daily dose of 25 mg. If needed the dose may be increased to 25 mg b.i.d. after at least 7 days, and again to 25 mg t.i.d. after an additional 7 days if necessary. Doses above 150 mg per day are not recommended. Consideration should be given to reducing ENKAID dosage if renal function deteriorates significantly.

Carcinogenesis, Mutagenesis, Impairment of Fertility

Carcinogenicity studies have been performed by the oral route in rats and mice at doses up to 30 mg/kg/day and 135 mg/kg/day, respectively. No drug-related increase in tumor incidence was observed. Bacterial and mammalian mutagenicity tests with encainide have been negative. No reduction in fertility occurred in rats at oral doses up to 14 mg/kg/day. Fertility was reduced when both male and female rats received oral doses of 28 mg/kg/day (approximately 13 times the average human dose) prior to mating; there was no reduction with treatment of each sex separately at the same dose.

Pregnancy Category B

Reproduction studies have been performed in rats and rabbits at doses up to 13 and 9 times the average human dose respectively and have revealed no evidence of harm to the fetus due to encainide. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers

Encainide is excreted in the milk of laboratory animals and has been reported to be present in human milk. Although no overt postnatal effects were observed in the postnatal phase of the rodent reproduction studies, other than decreased weight at the highest dose of 28 mg/kg/day (13 times human dose), the potential for serious adverse reactions in nursing infants from ENKAID is unknown. A decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use

The safety and effectiveness of ENKAID in children less than 18 years of age have not been established.

ADVERSE REACTIONS

The most serious adverse reactions reported for ENKAID are the provocation or aggravation of ventricular arrhythmias (See **WARNINGS**). These occurred during the course of the clinical research program in about 10% of the patients who received a wide range of doses under a variety of circumstances. In some cases this resulted in the development of sustained ventricular tachycardia or ventricular fibrillation.

Only 0.4% of patients discontinued ENKAID therapy due to congestive heart failure or related causes. Second- or third-degree AV block developed in 0.5% and 0.2% of the patients respectively. Sinus bradycardia, sinus pause or sinus arrest occurred in 1% of the patients. There have been rare reports of elevated serum liver enzymes (alkaline phosphatase, serum transaminases), hepatitis, and jaundice; in which a relation to encainide is possible and there has been one instance of a rechallenge-confirmed elevation of transaminases. There have also been rare reports of elevated blood glucose levels or of increased insulin requirements in diabetic patients. Although no cause and effect relationship has been established, caution is advised in patients who develop unexplained jaundice or signs of hepatic dysfunction or hyperglycemia and consideration should be given to discontinuing therapy.

In premarketing evaluations 2400 subjects were exposed to ENKAID, of whom more than 500 were maintained on drug for two years or longer. Adverse events were sufficiently troublesome to cause discontinuation in about 7% of the patients participating in premarketing clinical trials. The most frequently reported adverse events are dizziness, blurred or abnormal vision, and headache.

The most common adverse events reported by at least 3% of patients in controlled clinical trials, occurring at frequencies greater than those seen for patients on placebo, are chest pains, death, headache, lower extremity pain, proarrhythmia, abdominal pain, constipation, diarrhea, dry mouth, dyspepsia, nausea, dizziness, insomnia, somnolence, abnormal/blurred vision, and tinnitus.

OVERDOSAGE

Intentional or accidental overdosages with ENKAID have resulted in death.

Signs, Symptoms, and Laboratory Findings Associated with an Overdosage of the Drug

Overdosage with ENKAID may produce excessive widening of the QRS complex and QT interval and AV dissociation. Hypotension, bradycardia and finally asystole may develop. A variety of conduction disturbances may be observed. Convulsions have occurred in one case of intentional overdosage.

Oral LD_{50} of the Drug in Animals

The acute, oral LD_{50} values for encainide are estimated to be 80 mg/kg in the mouse and 59 mg/kg in the rat.

Recommended General Treatment Procedures

In the event of overdosage with ENKAID patients should be hospitalized and provided with cardiac monitoring and advanced life support systems. No specific antidote for ENKAID has been identified; however, one report has suggested hypertonic sodium bicarbonate may be useful in managing the cardiac toxicity associated with an ENKAID overdosage. Acute overdosages should be treated by gastric lavage followed by activated charcoal. Treatment of overdosage should be supportive.

DOSAGE AND ADMINISTRATION

As with other antiarrhythmic agents, ENKAID therapy in patients with sustained ventricular tachycardia should be initiated in a hospital setting with facilities for cardiac rhythm monitoring. Hospitalization is also recommended for patients with sinus node dysfunction or cardiomyopathy and/or congestive heart failure even if there is no history of sustained ventricular tachycardia, and at the time of a dose increase to 200 mg per day or above.

Dosages of ENKAID should be adjusted gradually allowing 3 to 5 days between dosing increments.

HOW SUPPLIED

Capsules, 25 mg, green and yellow hard gelatin capsule imprinted with ENKAID, 25 mg, Bristol and 732.
NDC0087-0732-41 Bottles of 100.
NDC0087-0732-42 Cartons of 100 Unit Dose.
Capsules, 35 mg, green and orange hard gelatin capsule imprinted with ENKAID, 35 mg, Bristol and 734.
NDC0087-0734-41 Bottles of 100.
NDC0087-0734-42 Cartons of 100 Unit Dose.
Capsules, 50 mg, green and brown hard gelatin capsules imprinted with ENKAID, 50 mg, Bristol and 735.
NDC0087-0735-41 Bottles of 100.
NDC0087-0735-42 Cartons of 100 Unit Dose.

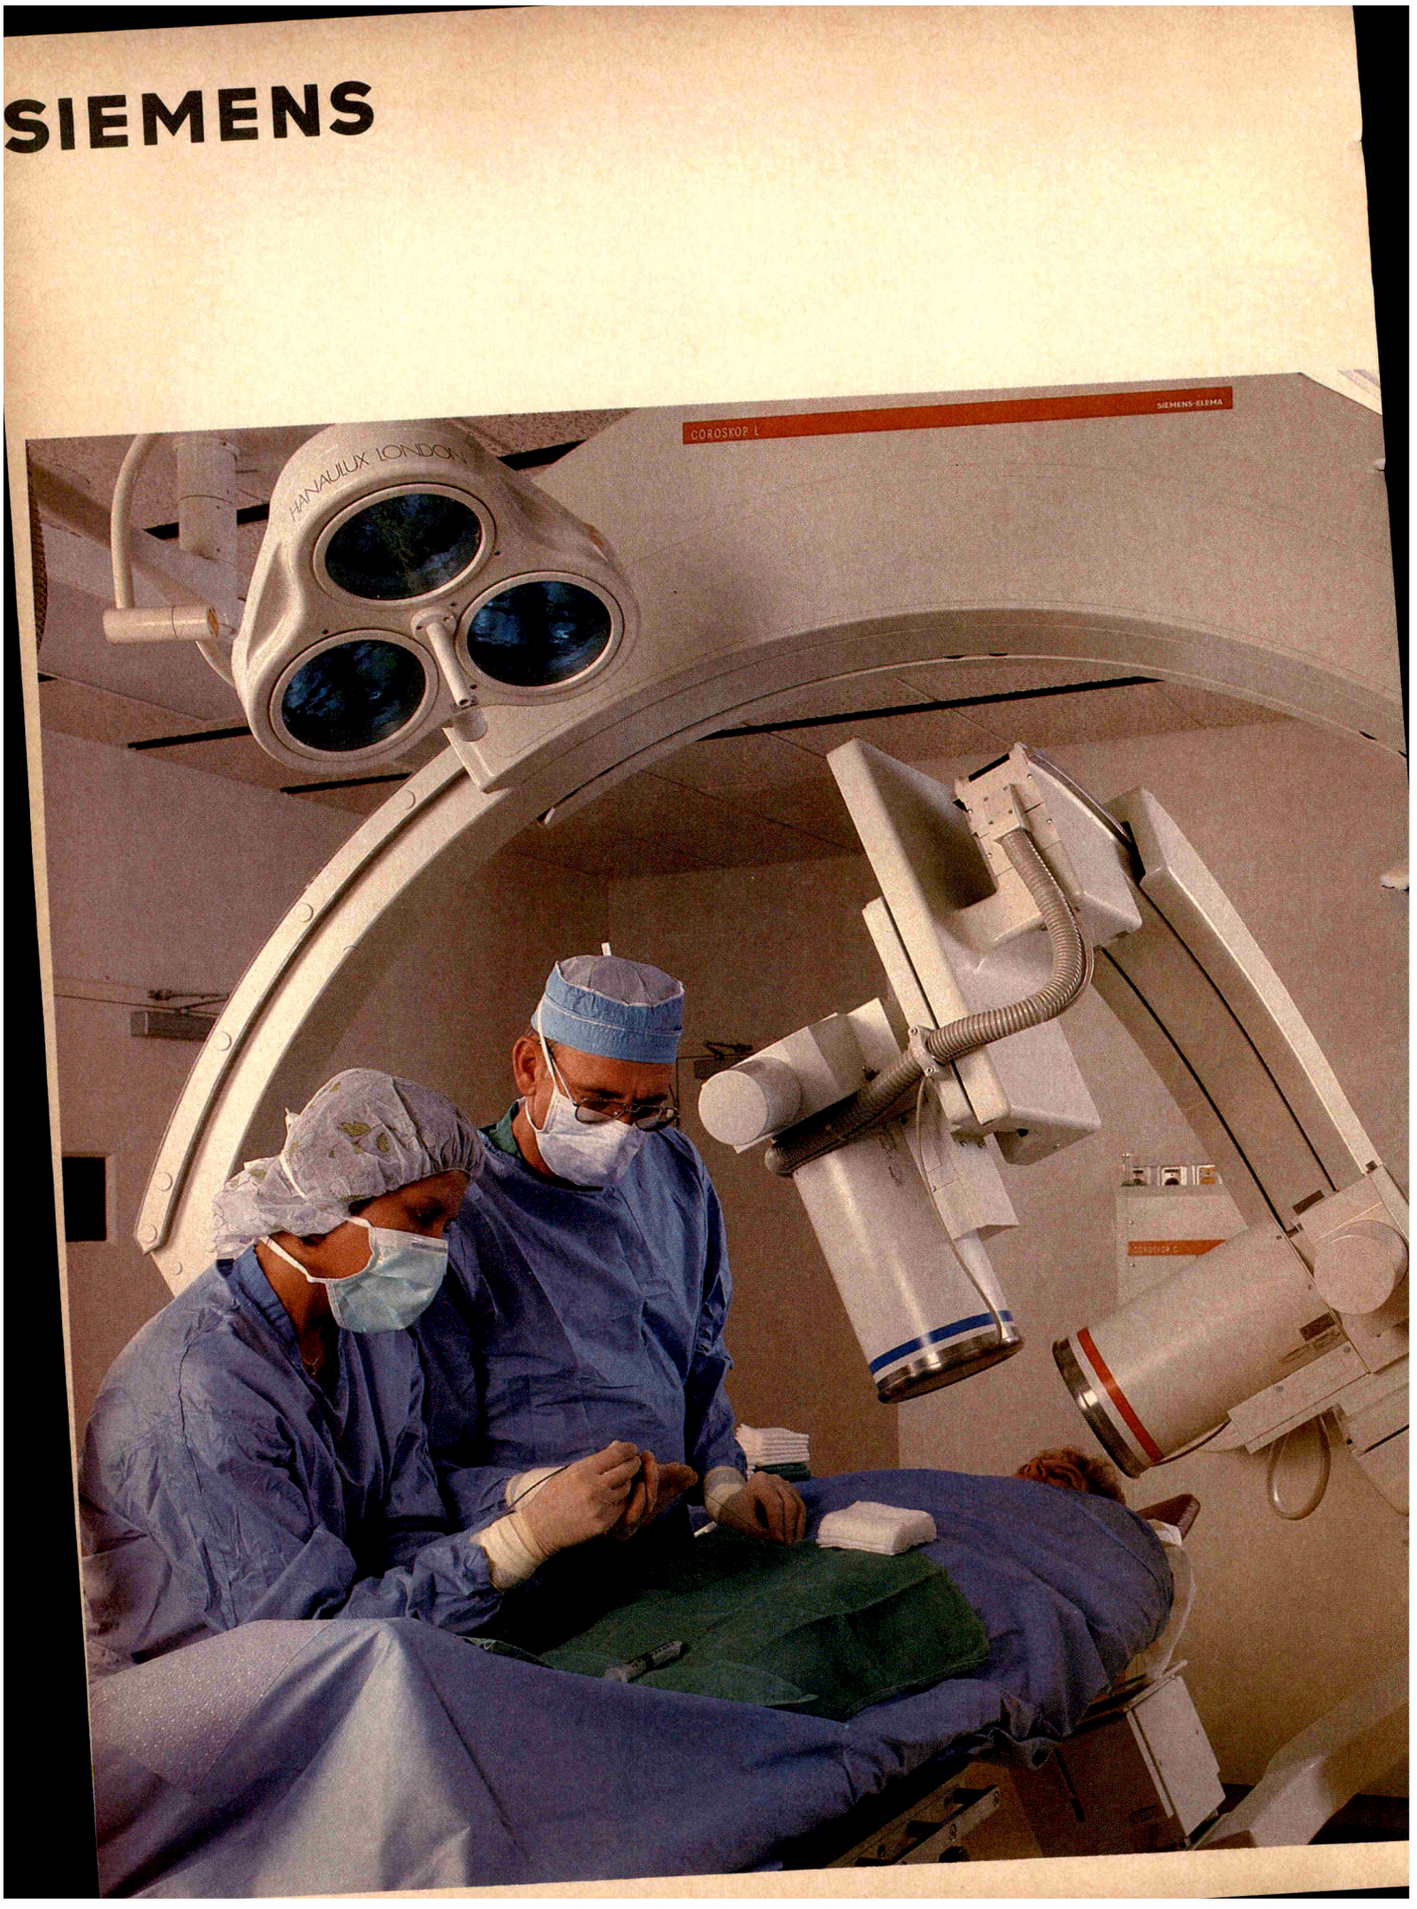
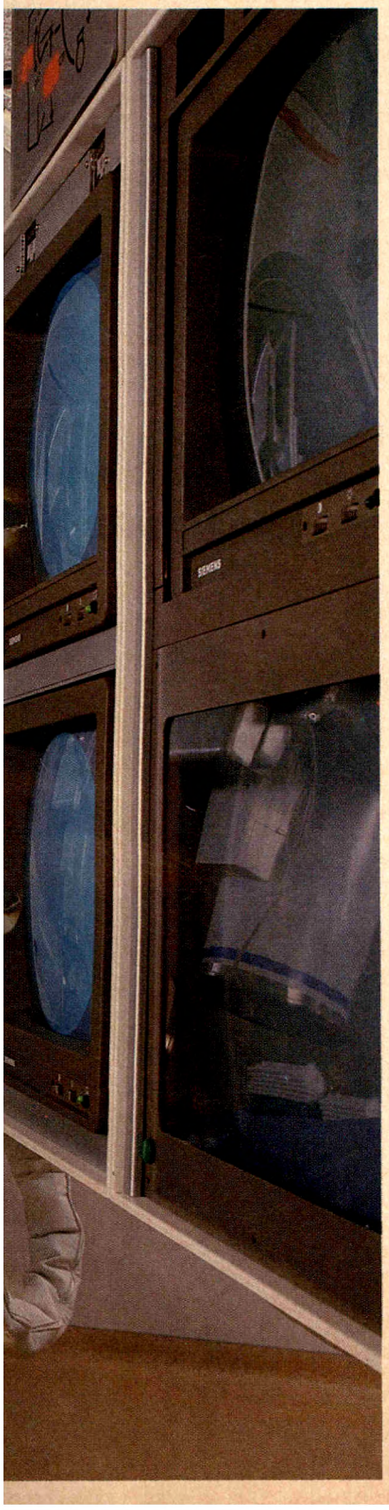
Made in U.S.A. #B-V-20 Revised June, 1987

SIEMENS



Two independent C-arm imaging units and other design innovations provide unparalleled free access to the patient; greater positioning range and better procedural control.



The BICOR cardiovascular imaging system... Clearly better, by design.

Unrestricted patient access
BICOR® is designed to give you more working room. Nothing comes between you and your patient. Nothing interferes with your clinical technique. You never have to settle for a femoral approach when you prefer the brachial...nor compete with equipment for head-of-table space to reach a child or trauma victim. The exclusive two independent C-arm design—freedom unique to the BICOR system.

Unlimited positioning range
The BICOR exclusive dual C-arm design also gives you greater operating versatility—more options and more positioning range. Even normally difficult compound angulations like spider or four-chamber views are easily obtained. And both C-arms operate in either p.a. or lateral projections—flexibility unique to the BICOR system.

Unequalled procedural control
BICOR incorporates many practical features to promote safe, efficient use. Sensor-touch function keys and joystick drive simplify operation and training. Unobstructed, overhead digital display of angulation data lets you see exactly where you are, and exactly where you should be in followup studies. And advanced microprocesor control prevents accidental collision of imaging components or patient contact during bi-plane positioning—sophistication unique to the BICOR system.

Complete support...systems and service
BICOR innovations reflect Siemens in-depth experience in the catheterization laboratory. In addition to the BICOR, we provide other related instrumentation including systems for digital imaging; physiological monitoring; computerized data management and a full range of image recording devices.

BICOR and all Siemens systems are backed with responsive, experienced support, installation, training and service.

Vaseretic®

(Enalapril Maleate-Hydrochlorothiazide|MSD)

For added hypertension control

- **Hydrochlorothiazide** augments the antihypertensive effect of enalapril.
- **Enalapril** tends to reverse the potassium loss often associated with hydrochlorothiazide.
- Highly effective in adults, regardless of age or race.*

This fixed-dose combination is not indicated for initial therapy. Patients already receiving a diuretic when enalapril is initiated or given a diuretic and enalapril simultaneously can develop symptomatic hypotension. In the initial titration of the individual entities, it is important, if possible, to stop the diuretic for several days before starting enalapril or, if this is not possible, to begin enalapri at a low initial dose (2.5 mg; see DOSAGE AND ADMINISTRATION). This fixed-dose combination is not suitable for titration but may be substituted for the individual components if the titrated doses are the same as those in the combination.

VASERETIC, containing 10 mg enalapril maleate and 25 mg hydrochlorothiazide, is contraindicated in patients who are hypersensitive to any component of this product. Because of the hydrochlorothiazide component, this product is contraindicated in patients with anuria or hypersensitivity to other sulfonamide-derived drugs.

Evaluation of the hypertensive patient should always include assessment of renal function.

*Although enalapril was antihypertensive in all races studied, black hypertensive patients (usually a low-renin hypertensive population) had a smaller average response to enalapril maleate monotherapy than non-black patients. In contrast, hydrochlorothiazide was more effective in black patients than enalapril. Concomitant administration of enalapril maleate and hydrochlorothiazide was equally effective in black and non-black patients.

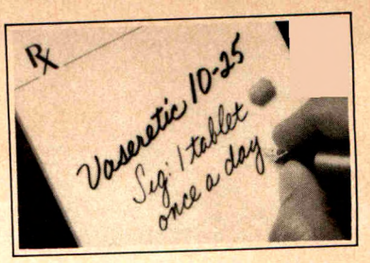
CE = angiotensin-converting enzyme

ease see the following page for a Brief Summary of Prescribing Information.

Once-A-Day
Vaseretic®
(Enalapril Maleate-Hydrochlorothiazide|MSD)



This fixed-dose combination is not indicated for initial therapy. Patients already receiving a diuretic when enalapril is initiated, or given a diuretic and enalapril simultaneously, can develop symptomatic hypotension. In the initial titration of the individual entities, it is important, if possible, to stop the diuretic for several days before starting enalapril or, if this is not possible, begin enalapril at a low initial dose (see DOSAGE AND ADMINISTRATION in complete Prescribing Information). This fixed-dose combination is not suitable for titration but may be substituted for the individual components if the titrated doses are the same as those in the combination.

CONTRAINDICATIONS

VASERETIC® (Enalapril Maleate-Hydrochlorothiazide, MSD) is contraindicated in patients who are hypersensitive to any component of this product. Because of the hydrochlorothiazide component, this product is contraindicated in patients with anuria or hypersensitivity to other sulfonamide-derived drugs.

WARNINGS

Hypotension: Excessive hypotension was rarely seen in uncomplicated hypertensive patients but is a possible consequence of enalapril use in severely salt/volume-depleted persons, such as those treated vigorously with diuretics or patients on dialysis. Syncope has been reported in 1.3% of patients receiving VASERETIC. In patients receiving enalapril alone, the incidence of syncope is 0.5%. The overall incidence of syncope may be reduced by proper titration of the individual components (see PRECAUTIONS, Drug Interactions; ADVERSE REACTIONS; and DOSAGE AND ADMINISTRATION in complete Prescribing Information). In patients with severe congestive heart failure, with or without associated renal insufficiency, excessive hypotension has been observed and may be associated with oliguria and/or progressive azotemia and rarely with acute renal failure and/or death. Because of the potential fall in blood pressure in these patients, therapy should be started under very close medical supervision. Such patients should be followed closely for the first two weeks of treatment and whenever the dose of enalapril and/or diuretic is increased.

If hypotension occurs, the patient should be placed in a supine position and, if necessary, receive an intravenous infusion of normal saline. A transient hypotensive response is not a contraindication to further doses, which usually can be given without difficulty once the blood pressure has increased after volume expansion.

Angioedema: Angioedema of the face, extremities, lips, tongue, glottis, and/or larynx has been reported in patients treated with angiotensin-converting-enzyme inhibitors, including enalapril. In such cases, VASERETIC should be promptly discontinued and the patient carefully observed until the swelling disappears. In instances where swelling has been confined to the face and lips the condition has generally resolved without treatment, although antihistamines have been useful in relieving symptoms. Angioedema associated with laryngeal edema may be fatal. **Where there is involvement of the tongue, glottis, or larynx, likely to cause airway obstruction, appropriate therapy, e.g., subcutaneous epinephrine solution 1:1000 (0.3 mL to 0.5 mL) should be promptly administered** (see ADVERSE REACTIONS).

Neutropenia/Agranulocytosis: Another angiotensin-converting-enzyme inhibitor has been shown to cause agranulocytosis and bone marrow depression, rarely in uncomplicated patients but more frequently in patients with renal impairment, especially if they also have a collagen vascular disease. Available data from clinical trials of enalapril are insufficient to show that enalapril does not cause agranulocytosis at similar rates. Foreign marketing experience has revealed several cases of neutropenia or agranulocytosis in which a causal relationship to enalapril cannot be excluded. Periodic monitoring of white blood cell counts in patients with collagen vascular disease and renal disease should be considered.

Hydrochlorothiazide: Thiazides should be used with caution in severe renal disease. In patients with renal disease, thiazides may precipitate azotemia. Cumulative effects of the drug may develop in patients with impaired renal function.

Thiazides should be used with caution in patients with impaired hepatic function or progressive liver disease, since minor alterations of fluid and electrolyte balance may precipitate hepatic coma.

Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma.

The possibility of exacerbation or activation of systemic lupus erythematosus has been reported.

Lithium generally should not be given with thiazides (see PRECAUTIONS, Drug Interactions; Hydrochlorothiazide).

PRECAUTIONS

General: ***Enalapril Maleate:*** *Impaired Renal Function:* As a consequence of inhibiting the renin-angiotensin-aldosterone system, changes in renal function may be anticipated in susceptible individuals. In patients with severe congestive heart failure whose renal function may depend on the activity of the renin-angiotensin-aldosterone system, treatment with angiotensin-converting-enzyme inhibitors, including enalapril, may be associated with oliguria and/or progressive azotemia and rarely with acute renal failure and/or death.

In clinical studies in hypertensive patients with unilateral or bilateral renal artery stenosis, increases in blood urea nitrogen and serum creatinine were observed in 20% of patients. These increases were almost always reversible upon discontinuation of enalapril and/or diuretic therapy. In such patients, renal function should be monitored during the first few weeks of therapy.

Some hypertensive patients with no apparent pre-existing renal vascular disease have developed increases in blood urea and serum creatinine, usually minor and transient, especially when enalapril has been given concomitantly with a diuretic. This is more likely to occur in patients with pre-existing renal impairment. Dosage reduction of enalapril and/or discontinuation of the diuretic may be required. **Evaluation of the hypertensive patient should always include assessment of renal function.**

Hyperkalemia: Elevated serum potassium (greater than 5.7 mEq/L) was observed in approximately 1% of hypertensive patients in clinical trials treated with enalapril alone. In most cases, these were isolated values which resolved despite continued therapy, although hyperkalemia was a cause of discontinuation of therapy in 0.28% of hypertensive patients. Hyperkalemia was less frequent (approximately 0.1%) in patients treated with enalapril plus hydrochlorothiazide. Risk factors for the development of hyperkalemia may include renal insufficiency, diabetes mellitus, and the concomitant use of agents to treat hypokalemia (see Drug Interactions).

Surgery/Anesthesia: In patients undergoing major surgery or during anesthesia with agents that produce hypotension, enalapril may block angiotensin II formation secondary to compensatory renin release. If hypotension occurs and is considered to be due to this mechanism, it can be corrected by volume expansion.

Hydrochlorothiazide: Periodic determination of serum electrolytes to detect possible electrolyte imbalance should be performed at appropriate intervals. All patients receiving thiazide therapy should be observed for clinical signs of fluid or electrolyte imbalance: namely hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Warning signs or symptoms of fluid and electrolyte imbalance, irrespective of cause, include dryness of mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains or cramps, muscular fatigue, hypotension, oliguria, tachycardia, and gastrointestinal disturbances such as nausea and vomiting.

Hypokalemia may develop, especially with brisk diuresis, when severe cirrhosis is present or after prolonged therapy. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Hypokalemia can sensitize or exaggerate the response of the heart to the toxic effects of digitalis (e.g., increased ventricular irritability). Because enalapril reduces the production of aldosterone, concomitant therapy with enalapril attenuates the diuretic-induced potassium loss (see Drug Interactions: Agents Increasing Serum Potassium).

Although any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease), chloride replacement may be required in the treatment of metabolic alkalosis.

Dilutional hyponatremia may occur in edematous patients in hot weather; appropriate therapy is water restriction rather than administration of salt except in rare instances when the hyponatremia is life-threatening. In actual salt depletion, appropriate replacement is the therapy of choice.

Hyperuricemia may occur or frank gout may be precipitated in certain patients receiving thiazide therapy.

In diabetic patients, dosage adjustments of insulin or oral hypoglycemic agents may be required. Hyperglycemia may occur with thiazide diuretics. Thus, latent diabetes mellitus may become manifest during thiazide therapy.

The antihypertensive effects of the drug may be enhanced in the postsympathectomy patient.

If progressive renal impairment becomes evident, consider withholding or discontinuing diuretic therapy.

Thiazides have been shown to increase the urinary excretion of magnesium; this may result in hypomagnesemia.

Thiazides may decrease urinary calcium excretion. Thiazides may cause intermittent and slight elevation of serum calcium in the absence of known disorders of calcium metabolism. Marked hypercalcemia may be evidence of hidden hyperparathyroidism. Thiazides should be discontinued before carrying out tests for parathyroid function.

Information for Patients: *Angioedema:* Angioedema, including laryngeal edema, may occur especially following the first dose of enalapril. Patients should be so advised and told to report immediately any signs or symptoms suggesting angioedema (swelling of face, extremities, eyes, lips, tongue and/or difficulty in breathing) and to take no more drug until they have consulted with the prescribing physician.

Hypotension: Patients should be cautioned to report lightheadedness especially during the first few days of therapy. If actual syncope occurs, patients should be told to discontinue the drug until they have consulted with the prescribing physician.

All patients should be cautioned that excessive perspiration and dehydration may lead to an excessive fall in blood pressure because of reduction in fluid volume. Other causes of volume depletion such as vomiting or diarrhea may also lead to a fall in blood pressure; patients should be advised to consult with the physician.

Hyperkalemia: Patients should be told not to use salt substitutes containing potassium without consulting their physician.

Neutropenia: Patients should be told to report promptly any indication of infection (e.g., sore throat, fever) which may be a sign of neutropenia.

NOTE: As with many other drugs, certain advice to patients being treated with VASERETIC® (Enalapril Maleate-Hydrochlorothiazide, MSD) is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects.

Drug Interactions: ***Enalapril Maleate:*** *Hypotension—Patients on Diuretic Therapy:* Patients on diuretics and especially those in whom diuretic therapy was recently instituted may occasionally experience an excessive reduction of blood pressure after initiation of therapy with enalapril. The possibility of hypotensive effects with enalapril can be minimized by either discontinuing the diuretic or increasing the salt intake prior to initiation of treatment with enalapril. If it is necessary to continue the diuretic, provide medical supervision for at least one hour after the initial dose (see WARNINGS and DOSAGE AND ADMINISTRATION). *Agents Causing Renin Release:* The antihypertensive effect of enalapril is augmented by antihypertensive agents that cause renin release (e.g., diuretics). *Other Cardiovascular Agents:* Enalapril has been used concomitantly with beta-adrenergic-blocking agents, methyldopa, nitrates, calcium-blocking agents, hydralazine, and prazosin without evidence of clinically significant adverse interactions. *Agents Increasing Serum Potassium:* Enalapril attenuates diuretic-induced potassium loss. Potassium-sparing diuretics (e.g., spironolactone, triamterene, or amiloride), potassium supplements, or potassium-containing salt substitutes may lead to significant increases in serum potassium. Therefore, if concomitant use of these agents is indicated, they should be used with caution and with frequent monitoring of serum potassium.

Hydrochlorothiazide: When administered concurrently, the following drugs may interact with thiazide diuretics. *Alcohol, barbiturates, or narcotics*—potentiation of orthostatic hypotension may occur. *Antidiabetic drugs (oral agents and insulin)*—dosage adjustment of the antidiabetic drug may be required. *Other antihypertensive drugs*—additive effect or potentiation. *Corticosteroids, ACTH*—intensified electrolyte depletion, particularly hypokalemia. *Pressor amines (e.g., norepinephrine)*—possible decreased response to pressor amines but not sufficient to preclude their use. *Skeletal muscle relaxants, nondepolarizing (e.g., tubocurarine)*—possible increased responsiveness to the muscle relaxant. *Lithium*—should not generally be given with diuretics. Diuretic agents reduce the renal clearance of lithium and add a high risk of lithium toxicity. Refer to the package insert for lithium preparations before use of such preparations with VASERETIC. *Nonsteroidal anti-inflammatory drugs*—In some patients, the administration of a nonsteroidal anti-inflammatory agent can reduce the diuretic, natriuretic, and antihypertensive effects of loop, potassium-sparing, and thiazide diuretics. Therefore, when VASERETIC and nonsteroidal anti-inflammatory agents are used concomitantly, the patient should be observed closely to determine if the desired effect of the diuretic is obtained.

Pregnancy: ***Enalapril Maleate-Hydrochlorothiazide:*** *Pregnancy Category C.* There was no teratogenicity in rats given up to 90 mg/kg/day of enalapril (150 times the maximum human dose) in combination with 10 mg/kg/day of hydrochlorothiazide (2-1/2 times the maximum human dose) or in mice given up to 30 mg/kg/day of enalapril (50 times the maximum human dose) in combination with 10 mg/kg/day of hydrochlorothiazide (2-1/2 times the maximum human dose). At these doses, fetotoxicity expressed as a decrease in average fetal weight occurred in both species. No fetotoxicity occurred at lower doses; 30/10 mg/kg/day of enalapril-hydrochlorothiazide in rats and 10/10 mg/kg/day of enalapril-hydrochlorothiazide in mice.

There are no adequate and well-controlled studies in pregnant women. VASERETIC® (Enalapril Maleate-Hydrochlorothiazide, MSD) should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Hydrochlorothiazide: Thiazides cross the placental barrier and appear in cord blood. *Nonteratogenic Effects:* These may include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult.

Nursing Mothers: It is not known whether enalapril is secreted in human milk, however, thiazides do appear in human milk. Because of the potential for serious reactions in nursing infants from hydrochlorothiazide, a decision should be made whether to discontinue nursing or to discontinue VASERETIC, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

VASERETIC has been evaluated for safety in more than 1,500 patients, including over 300 patients treated for one year or more.

In clinical trials with VASERETIC, no adverse experiences peculiar to this combination drug have been observed. Adverse experiences that have occurred have been limited to those that have been previously reported with enalapril or hydrochlorothiazide.

The most frequent clinical adverse experiences in controlled trials were: dizziness (8.6%), headache (5.5%), fatigue (3.9%), and cough (3.5%). Generally, adverse experiences were mild and transient in nature.

Adverse experiences occurring in greater than 2% of patients treated with VASERETIC in controlled clinical trials are shown below:

	Percent of Patients in Controlled Studies	
	VASERETIC (n = 1,580) Incidence (discontinuation)	Placebo (n = 230) Incidence
Dizziness	8.6(0.7)	4.3
Headache	5.5(0.4)	9.1
Fatigue	3.9(0.8)	2.6
Cough	3.5(0.4)	0.9
Muscle Cramps	2.7(0.2)	0.9
Nausea	2.5(0.4)	1.7
Asthenia	2.4(0.3)	0.9
Orthostatic Effects	2.3(<0.1)	0.0
Impotence	2.2(0.5)	0.5
Diarrhea	2.1(<0.1)	1.7

Clinical adverse experiences occurring in 0.5% to 2.0% of patients in controlled trials included: *Cardiovascular:* Syncope, orthostatic hypotension, palpitations, chest pain, tachycardia. *Nervous System:* Insomnia, nervousness, paresthesia, somnolence, vertigo. *Gastrointestinal System:* Abdominal pain, vomiting, dyspepsia, constipation, flatulence, dry mouth. *Other:* Dyspnea, gout, back pain, arthralgia, hyperhidrosis, pruritus, decreased libido, rash, tinnitus, urinary tract infection. *Angioedema:* Angioedema has been reported in patients receiving VASERETIC (0.6%). Angioedema associated with laryngeal edema may be fatal. If angioedema of the face, extremities, lips, tongue, glottis, and/or larynx occurs, treatment with VASERETIC should be discontinued and appropriate therapy instituted immediately (see WARNINGS). *Hypotension:* In clinical trials, adverse effects relating to hypotension occurred as follows: hypotension (0.9%), orthostatic hypotension (1.5%), other orthostatic effects (2.3%). In addition, syncope occurred in 1.3% of patients (see WARNINGS).

Clinical Laboratory Test Findings: *Serum Electrolytes:* See PRECAUTIONS. *Creatinine, Blood Urea Nitrogen:* In controlled clinical trials, minor increases in blood urea nitrogen and serum creatinine, reversible upon discontinuation of therapy, were observed in about 0.6% of patients with essential hypertension treated with VASERETIC. More marked increases have been reported in other enalapril experience. Increases are more likely to occur in patients with renal artery stenosis (see PRECAUTIONS). *Serum Uric Acid, Glucose, Magnesium, and Calcium:* See PRECAUTIONS. *Hemoglobin and Hematocrit:* Small decreases in hemoglobin and hematocrit (mean decreases of approximately 0.3 g % and 1.0 vol %, respectively) occur frequently in hypertensive patients treated with VASERETIC but are rarely of clinical importance unless another cause of anemia coexists. In clinical trials, less than 0.1% of patients discontinued therapy due to anemia. *Other (Causal Relationship Unknown):* Rarely, elevations of liver enzymes and/or serum bilirubin have occurred.

Other adverse reactions that have been reported with the individual components are listed below: *Enalapril Maleate*—Enalapril has been evaluated for safety in more than 10,000 patients. In clinical trials, adverse reactions which occurred with enalapril were also seen with VASERETIC. However, since enalapril has been marketed, the following adverse reactions have been reported: *Renal:* Renal dysfunction, renal failure, oliguria; *Hematologic:* Rare cases of neutropenia, thrombocytopenia, and bone marrow depression have been reported in which a causal relationship to enalapril cannot be excluded. *Hydrochlorothiazide—Body as a Whole:* Weakness; *Digestive:* Anorexia, gastric irritation, cramping, jaundice (intrahepatic cholestatic jaundice), pancreatitis, sialadenitis; *Hematologic:* Leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia, hemolytic anemia; *Musculoskeletal:* Muscle spasm; *Nervous System/Psychiatric:* Restlessness; *Special Senses:* Transient blurred vision, xanthopsia; *Hypersensitivity:* Purpura, photosensitivity, urticaria, necrotizing angiitis (vasculitis and cutaneous vasculitis), fever, respiratory distress including pneumonitis and pulmonary edema, anaphylactic reactions.

HOW SUPPLIED

No. 3418—Tablets VASERETIC 10-25, are red, squared capsule-shaped, compressed tablets, coded MSD 720 on one side and VASERETIC on the other. Each tablet contains 10 mg enalapril maleate and 25 mg hydrochlorothiazide. They are supplied as follows:

NDC 0006-0720-68 bottles of 100 (with desiccant).

Calan® Tablets (verapamil HCl) 120 mg 80 mg

BRIEF SUMMARY

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure<90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block (if no pacemaker is present), atrial flutter/fibrillation with an accessory bypass tract (eg, WPW or LGL syndromes).

Warnings: Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction<30%) or moderate to severe symptoms of cardiac failure and in patients with any degree of ventricular dysfunction if they are receiving a beta-adrenergic blocker. Control milder heart failure with optimum digitalization and/or diuretics before Calan is used. Verapamil may occasionally produce a decrease in blood pressure below normal levels, which may result in dizziness or symptomatic hypotension. Elevations of liver enzymes have been reported. Several cases of hepatocellular injury have been demonstrated to be produced by verapamil. Periodic monitoring of liver function in patients on verapamil is prudent. Some patients with paroxysmal and/or chronic atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) have developed an increased antegrade conduction across the accessory pathway bypassing the AV node, producing a very rapid ventricular response or ventricular fibrillation after receiving I.V. verapamil (or digitalis). Because of this risk, oral verapamil is contraindicated in such patients. The effect of verapamil on AV conduction and the SA node may cause asymptomatic 1st-degree AV block and transient bradycardia, sometimes with nodal escape rhythms. PR-interval prolongation is correlated with verapamil plasma concentrations especially during initial titration. Higher degrees of AV block are infrequent (0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil.

Precautions: Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Verapamil may decrease neuromuscular transmission in patients with Duchenne's muscular dystrophy and may prolong recovery from the neuromuscular blocking agent vecuronium. It may be necessary to decrease verapamil dosage in patients with attenuated neuromuscular transmission. Studies in a small number of patients suggest that concomitant use of Calan and oral beta-adrenergic blockers may be beneficial in certain patients with chronic stable angina or hypertension. Combined therapy can also have adverse effects on cardiac function; therefore patients should be closely monitored. A decrease in metoprolol clearance may occur with concurrent use of verapamil and metoprolol. Chronic verapamil treatment increases serum digoxin levels by 50% to 75% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient reassessed. Verapamil used concomitantly with oral antihypertensive agents will usually have an additive effect on lowering blood pressure that in some cases may be excessive; therefore patients should be monitored appropriately. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Quinidine levels may increase during verapamil therapy. Clearance of verapamil may be reduced in concomitant use with cimetidine. Concomitant use of verapamil and lithium may result in decreased serum lithium levels. Verapamil therapy may increase carbamazepine concentrations during combined use. Therapy with rifampin may markedly reduce oral verapamil bioavailability. Concomitant use of inhalation anesthetics and calcium antagonists needs careful titration to avoid excessive cardiovascular depression. Verapamil may potentiate the activity of neuromuscular blocking agents (curare-like and depolarizing); dosage reduction may be required. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Another study in rats showed no evidence of carcinogenicity. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. Verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use. Safety and efficacy in children under 18 have not been established.

Adverse Reactions— oral verapamil: Constipation (8.4%), dizziness (3.5%), nausea (2.7%), hypotension (2.5%), edema (2.1%), headache (1.9%), CHF/pulmonary edema (1.8%), fatigue (1.7%), bradycardia: HR <50/min (1.4%), AV block: total 1°, 2°, 3° (1.3%)/3rd-degree (0.8%), flushing (0.1%); elevations of liver enzymes have been reported (see *Warnings*). The following reactions, reported in 1.0% or less of patients, occurred under circumstances where a causal relationship is not certain: angina pectoris, chest pain, claudication, myocardial infarction, palpitations, purpura (vasculitis), syncope, diarrhea, dry mouth, gastrointestinal distress, gingival hyperplasia, ecchymosis or bruising, confusion, equilibrium disorders, insomnia, muscle cramps, paresthesia, psychotic symptoms, shakiness, somnolence, dyspnea, arthralgia, rash, exanthema, hair loss, hyperkeratosis, macules, sweating, urticaria, blurred vision, gynecomastia, impotence, increased urination, spotty menstruation.

Practical New Books in Cardiology From Yorke Medical Books

Manual of Cardiac Arrhythmias

BY EDWARD K. CHUNG, M.D., F.A.C.P., F.A.C.C. 0-914316-43-5, November 1985, appx. 324 pp., $30.00

The eminent clinician, professor, and medical writer Dr. Edward K. Chung, has produced the most current "how to" manual on cardiac arrhythmias. The book has been formatted and edited to facilitate its use as a ready reference to up-to-date material on diagnosing and managing arrhythmias commonly seen in daily clinical practice. Its purpose is not to discuss in-depth every aspect of various cardiac rhythm problems, but rather to provide the reader with a concise easy-to-use guide. An invaluable resource for all physicians and allied health professionals seeking to add to their clinical knowledge of a complex topic without the necessity of purchasing a large general text on cardiology.

Cardiac Arrhythmias

Self Learning Companion Volume to Manual of Cardiac Arrhythmias

BY EDWARD K. CHUNG, M.D., F.A.C.P., F.A.C.C. 0-914316-46-X, November 1985, appx. 440 pp., $30.00

Conceived by Dr. Chung as a companion volume to Manual of Cardiac Arrhythmias, this book includes 200 cases showing common cardiac arrhythmias frequently encountered in clinical practice.

Interpretation of the ECG training is aided by short case histories. The reverse side of each page gives a full analysis of the interpretation of the tracing, enabling readers to assess their own ECG diagnosis. In the majority of cases, three simultaneous ECG leads (leads V, II, and V_5) recorded by 3-channel ECG equipment, are shown for accurate diagnosis. In addition to the ECG diagnosis, the pertinent clinical significance and therapeutic approach are included in many instances.

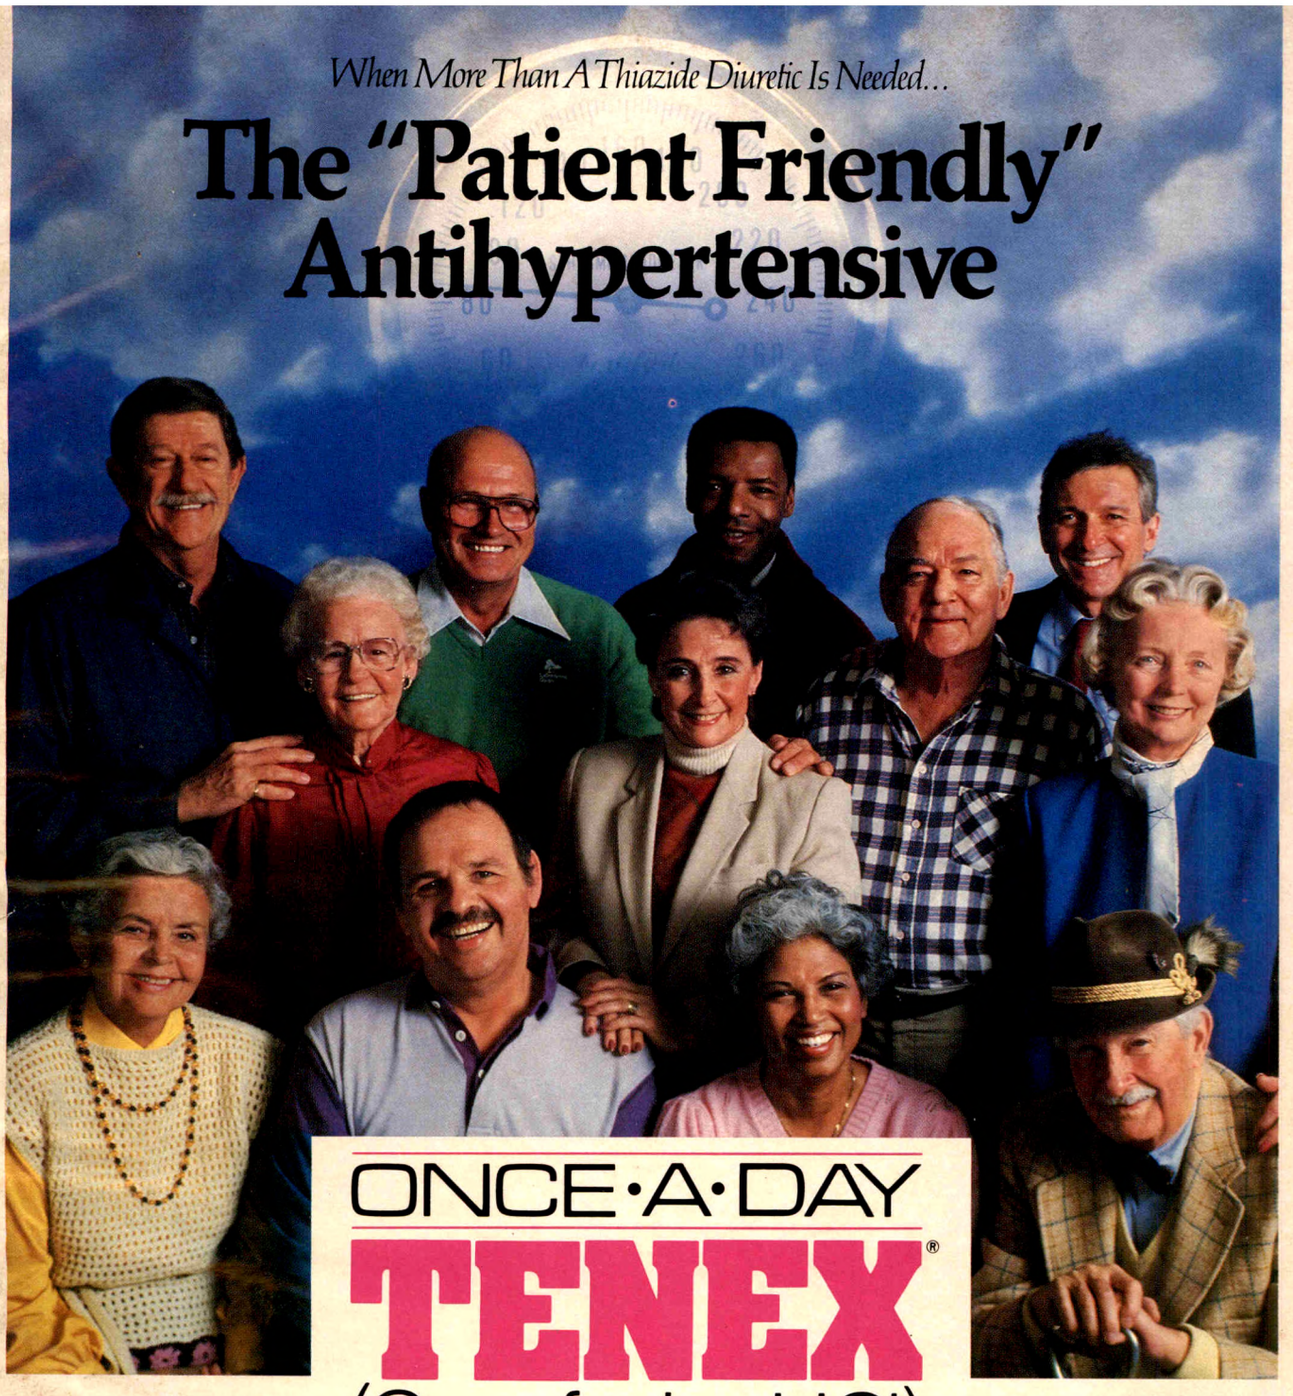
When More Than A Thiazide Diuretic Is Needed...

The "Patient Friendly" Antihypertensive



ONCE·A·DAY TENEX® (Guanfacine HCl)

- A side effect profile at 1 mg/day comparable to placebo
  Fewer patient complaints
- 1 mg a day — optimal dosage for most patients
  Most patients will not require dose titration
- Once a day, for 24-hour control
  Convenience and compliance
- Suitable for a wide range of patients

Please see adjacent page for brief summary.

The "Patient Friendly" Antihypertensive

ONCE·A·DAY TENEX® (Guanfacine HCl)

The following is a brief summary only. Before prescribing, see complete prescribing information in Tenex product labeling.

Contraindications: Tenex is contraindicated in patients with known hypersensitivity to guanfacine hydrochloride.

Precautions: *General.* Like other antihypertensive agents, Tenex (guanfacine hydrochloride) should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal or hepatic failure.

Sedation. Tenex, like other orally active central alpha-2 adrenergic agonists, causes sedation or drowsiness, especially when beginning therapy. These symptoms are dose-related (see Adverse Reactions). When Tenex is used with other centrally active depressants (such as phenothiazines, barbiturates, or benzodiazepines), the potential for additive sedative effects should be considered.

Rebound. Abrupt cessation of therapy with orally active central alpha-2 adrenergic agonists may be associated with increases (from depressed on-therapy levels) in plasma and urinary catecholamines, symptoms of "nervousness and anxiety" and, less commonly, increases in blood pressure to levels significantly greater than those prior to therapy.

Information for Patients. Patients who receive Tenex should be advised to exercise caution when operating dangerous machinery or driving motor vehicles until it is determined that they do not become drowsy or dizzy from the medication. Patients should be warned that their tolerance for alcohol and other CNS depressants may be diminished. Patients should be advised not to discontinue therapy abruptly.

Laboratory Tests. In clinical trials, no clinically relevant laboratory test abnormalities were identified as causally related to drug during short-term treatment with Tenex (guanfacine hydrochloride).

Drug Interactions. No specific adverse drug interactions have been identified, but the potential for increased sedation when Tenex is given with other CNS-depressant drugs should be appreciated.

Anticoagulants. Ten patients who were stabilized on oral anticoagulants were given guanfacine, 1–2 mg/day, for 4 weeks. No changes were observed in the degree of anticoagulation.

In several well-controlled studies, guanfacine was administered together with diuretics with no drug interactions reported. In the long-term safety studies, Tenex was given concomitantly with many drugs without evidence of any interactions. The principal drugs given (number of patients in parentheses) were: cardiac glycosides (115), sedatives and hypnotics (103), coronary vasodilators (52), oral hypoglycemics (45), cough and cold preparations (45), NSAIDs (38), antihyperlipidemics (29), antigout drugs (24), oral contraceptives (18), bronchodilators (13), insulin (10), and beta blockers (10).

Drug/Laboratory Test Interactions. No laboratory test abnormalities related to the use of Tenex (guanfacine hydrochloride) have been identified.

Carcinogenesis, Mutagenesis, Impairment of Fertility. No carcinogenic effect was observed in studies of 78 weeks in mice at doses more than 150 times the maximum recommended human dose and 102 weeks in rats at doses more than 100 times the maximum recommended human dose. In a variety of test models guanfacine was not mutagenic.

No adverse effects were observed in fertility studies in male and female rats.

Pregnancy Category B. Administration of guanfacine to rats at 70 times the maximum recommended human dose and rabbits at 20 times the maximum recommended human dose resulted in no evidence of impaired fertility or harm to the fetus. Higher doses (100 and 200 times the maximum recommended human dose in rabbits and rats respectively) were associated with reduced fetal survival and maternal toxicity. Rat experiments have shown that guanfacine crosses the placenta.

There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Labor and Delivery. Tenex (guanfacine hydrochloride) is not recommended in the treatment of acute hypertension associated with toxemia of pregnancy. There is no information available on the effects of guanfacine on the course of labor and delivery.

Nursing Mothers. It is not known whether Tenex (guanfacine hydrochloride) is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Tenex is administered to a nursing woman. Experiments with rats have shown that guanfacine is excreted in the milk.

Pediatric Use. Safety and effectiveness in children under 12 years of age have not been demonstrated. Therefore, the use of Tenex in this age group is not recommended.

Adverse Reactions: Adverse reactions noted with Tenex (guanfacine hydrochloride) are similar to those of other drugs of the central α-2 adrenoreceptor agonist class: dry mouth, sedation (somnolence), weakness (asthenia), dizziness, constipation, and impotence. While the reactions are common, most are mild and tend to disappear on continued dosing.

In a 12-week placebo-controlled, dose-response study the frequency of the most commonly observed adverse reactions showed a clear dose relationship from 0.5 to 3 mg, as follows:

Adverse Reaction	Assigned Treatment Group				
	Placebo	0.5 mg	1.0 mg	2.0 mg	3.0 mg
n =	73	72	72	72	72
Dry Mouth	5 (7%)	4 (5%)	6 (8%)	8 (11%)	20 (28%)
Somnolence	1 (1%)	3 (4%)	0 (0%)	1 (1%)	10 (14%)
Asthenia	0 (0%)	2 (3%)	0 (0%)	2 (2%)	7 (10%)
Dizziness	2 (2%)	1 (1%)	3 (4%)	6 (8%)	3 (4%)
Headache	3 (4%)	4 (3%)	3 (4%)	1 (1%)	2 (2%)
Impotence	1 (1%)	1 (1%)	0 (0%)	1 (1%)	3 (4%)
Constipation	0 (0%)	0 (0%)	0 (0%)	1 (1%)	1 (1%)
Fatigue	3 (3%)	2 (3%)	2 (3%)	5 (6%)	3 (4%)

There were 41 premature terminations because of adverse reactions in this study. The percent of patients who terminated and the dose at which they terminated were as follows:

Dose:	Placebo	0.5 mg	1 mg	2 mg	3 mg
Terminated:	6.9%	4.2%	3.2%	6.9%	8.3%

Reasons for dropouts among patients who received guanfacine were: somnolence, headache, weakness, dry mouth, dizziness, impotence, insomnia, constipation, syncope, urinary incontinence, conjunctivitis, paresthesia, and dermatitis.

In a second placebo-controlled study in which the dose could be adjusted upward to 3 mg per day in 1-mg increments at 3-week intervals, i.e., a setting more similar to ordinary clinical use, the most commonly recorded reactions were: dry mouth 47%, constipation 16%, fatigue 12%, somnolence 10%, asthenia 6%, dizziness 6%, headache 4%, and insomnia 4%.

Reasons for dropouts among patients who received guanfacine were: somnolence, dry mouth, dizziness, impotence, constipation, confusion, depression, and palpitations.

In the clonidine/guanfacine comparison described in Clinical Pharmacology, the most common adverse reactions noted were:

	Guanfacine (n=279)	Clonidine (n=278)
Dry mouth	30%	37%
Somnolence	21%	35%
Dizziness	11%	8%
Constipation	10%	5%
Fatigue	9%	8%
Headache	4%	4%
Insomnia	4%	3%

Adverse reactions occurring in 3% or less of patients in the three controlled trials were:

Cardiovascular—	bradycardia, palpitations, substernal pain
Gastrointestinal—	abdominal pain, diarrhea, dyspepsia, dysphagia, nausea
CNS—	amnesia, confusion, depression, insomnia, libido decrease
ENT disorders—	rhinitis, taste perversion, tinnitus
Eye disorders—	conjunctivitis, iritis, vision disturbance
Musculoskeletal—	leg cramps, hypokinesia
Respiratory—	dyspnea
Dermatologic—	dermatitis, pruritus, purpura, sweating
Urogenital—	testicular disorder, urinary incontinence
Other—	malaise, paresthesia, paresis

Adverse reaction reports tend to decrease over time. In an open-label trial of one year's duration, 580 hypertensive subjects were given guanfacine, titrated to achieve goal blood pressure, alone (51%), with diuretic (38%), with beta blocker (3%), with diuretic plus beta blocker (6%), or with diuretic plus vasodilator (2%). The mean daily dose of guanfacine reached was 4.7 mg.

Adverse Reaction	Incidence of adverse reactions at any time during the study	Incidence of adverse reactions at end of one year
	n = 580	n = 580
Dry mouth	60%	15%
Drowsiness	33%	6%
Dizziness	15%	1%
Constipation	14%	3%
Weakness	5%	1%
Headache	4%	0.2%
Insomnia	5%	0%

There were 52 (8.9%) dropouts due to adverse effects in this 1-year trial. The causes were: dry mouth (n = 20), weakness (n = 12), constipation (n = 7), somnolence (n = 3), nausea (n = 3), orthostatic hypotension (n = 2), insomnia (n = 1), rash (n = 1), nightmares (n = 1), headache (n = 1), and depression (n = 1).

Drug Abuse and Dependence: No reported abuse or dependence has been associated with the administration of Tenex (guanfacine hydrochloride).

Dosage and Administration: The recommended dose of Tenex (guanfacine hydrochloride) is 1 mg daily given at bedtime to minimize somnolence. Patients should already be receiving a thiazide type diuretic.

If after 3 to 4 weeks of therapy, 1 mg does not give a satisfactory result, doses of 2 and then subsequently 3 mg may be given, although most of the effect of Tenex is seen at 1 mg (see Clinical Pharmacology). Some patients may show a rise in pressure toward the end of the dosing interval; in this event a divided dose may be utilized.

Higher daily doses (rarely up to 40 mg/day, in divided doses) have been used, but adverse reactions increase significantly with doses above 3 mg/day and there is no evidence of increased efficacy. No studies have established an appropriate dose or dosing interval when Tenex (guanfacine hydrochloride) is given as the sole antihypertensive agent.

The frequency of rebound hypertension is low, but rebound can occur. When rebound occurs, it does so after 2–4 days, which is delayed compared with clonidine hydrochloride. This is consistent with the longer half-life of guanfacine. In most cases, after abrupt withdrawal of guanfacine, blood pressure returns to pretreatment levels slowly (within 2–4 days) without ill effects.

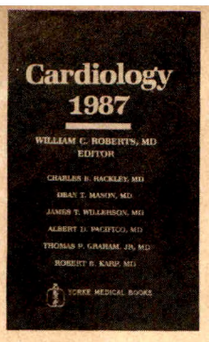
TE-K5RI, 8/87,



NEW 1987 EDITION!

Cardiology 1987, edited by William C. Roberts, M.D., brings you the most important, most recent developments in clinical cardiology—in one volume. Featuring a concise, easy-to-read format, **Cardiology 1987** summarizes 858 of the most significant articles published in 1986—from 25 of the world's leading journals. **Cardiology 1987:** order your copy today!

TABLE OF CONTENTS
(Selected)

- Factors Causing or Accelerating Coronary Arterial Atherosclerosis
- Coronary Artery Disease
- Acute Myocardial Infarction and Its Consequences
- Systemic Hypertension
- Arrhythmias, Conduction Disturbances and Cardiac Arrest
- Valvular Heart Disease
- Myocardial Heart Disease
- Congenital Heart Disease
- Congestive Heart Failure

517 pages $55.00 ISBN 0-914316-53-2

THE UNIVERSITY OF MICHIGAN MEDICAL SCHOOL
PRESENTS

MYOCARDIAL REPERFUSION 1988: PRACTICAL CONSIDERATIONS

Program Co-Chairmen: ***ERIC J. TOPOL, MD, FACC***
ROBERT M. CALIFF, MD, FACC

SATURDAY, MARCH 26, 1988
WESTIN PEACHTREE PLAZA, ATLANTA, GEORGIA
PRECEDING THE ACC SCIENTIFIC SESSIONS

Now that the benefits of thrombolytic therapy for acute myocardial infarction are evident, what are the practical aspects of its use? An international panel of experts at this workshop will consider the timing and safety of adjuvant mechanical interventions, the latest results from new clinical trials, and the future directions for reperfusion therapy, among other topics.

The University of Michigan Medical School is accredited by the ACCME to provide continuing medical education for physicians. The program is made possible by an educational grant from Genentech, Inc.

For further information, contact the University of Michigan Medical School, Office of Continuing Medical Education, G-1100 Towsley Center, Box 0201, Ann Arbor, Michigan 48109-0201 (313–763-1400).

CIBA-CORNING introduces...

CK-MB accuracy at the speed of Lite

Results in as little as one hour

Critical data for diagnosing/confirming acute MI

Half the time of electrophoresis

Results that are accurate

No false positives due to cross-reactivity with CK-MM or CK-BB[1,2]

Results that can monitor progress of TPA and other thrombolytic agents

Magic® Lite

Magnetic Immuno Chemistries

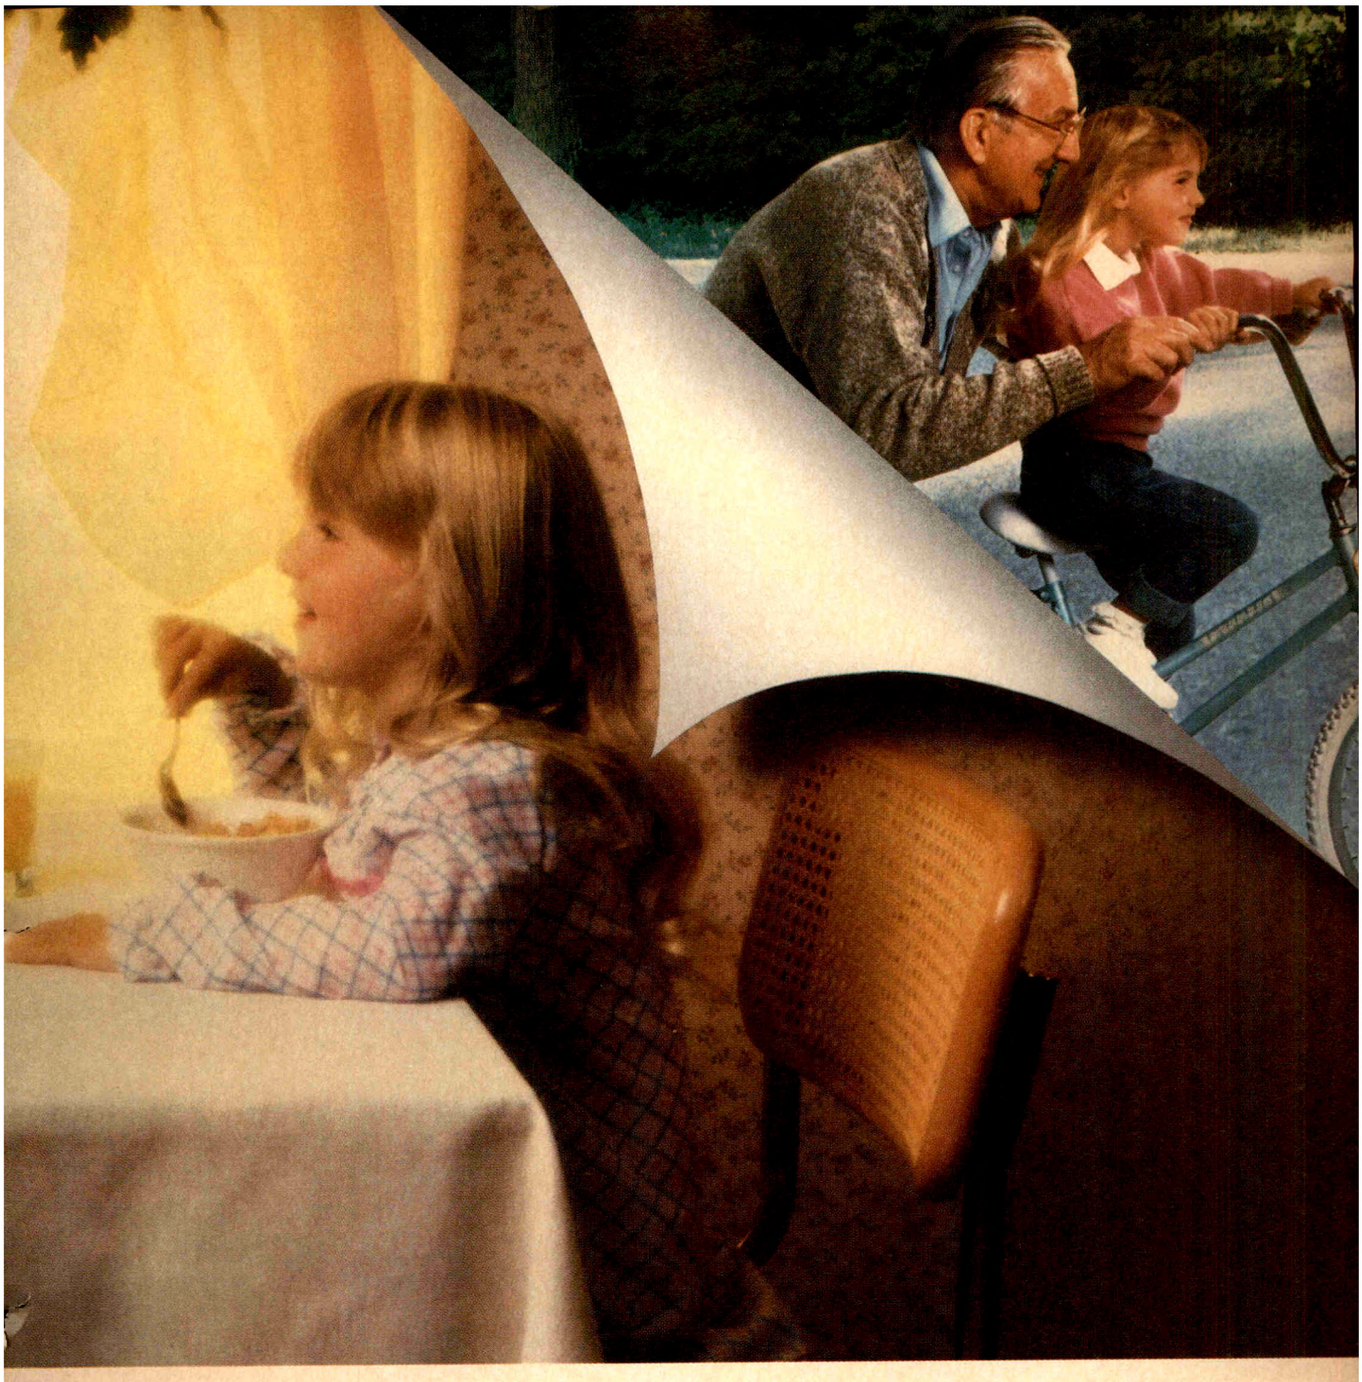
099-6512-A

In the unpredictable world of angina, there is an antianginal you can count on...

24 HOURS A DAY



Angina attacks can occur any time: in the early morning hours, upon awakening; in the evening; or at any time during the day, triggered by exertion.

Of course, no one *plans* an angina attack. But protection *can* be planned.

CORGARD (nadolol tablets), with just a single daily dose, provides clinically proven, 24-hour protection for your patients.[1-3]

CORGARD®
(nadolol tablets)

Because no time is a good time for angina

Please see brief summary on the adjacent page.

CORGARD®
(nadolol tablets)

24-hour protection...because no time is a good time for angina

CORGARD® TABLETS
Nadolol Tablets USP

DESCRIPTION: CORGARD (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure—Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2- week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery—Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia—Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis—Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Renal Function—Use nadolol with caution (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients—Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign of impending failure. Advise patients in event of missed doses.

Drug Interactions—Concurrent administration may result in interactions with: Anesthetics, general—exaggeration of the hypotension induced by general anesthetics (see WARNINGS, Major Surgery). Antidiabetic drugs (oral agents and insulin)—hypoglycemia or hyperglycemia; adjust antidiabetic drug dosage accordingly (see WARNINGS, Diabetes and Hypoglycemia). Catecholamine-depleting drugs (e.g., reserpine)—additive effect; monitor closely for hypotension and/or excessive bradycardia.

Carcinogenesis, Mutagenesis, Impairment of Fertility—In 1 to 2 year oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy Category C—In animal reproduction studies with nadolol, evidence of embryo- and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus. Neonates of mothers who received nadolol at parturition have exhibited bradycardia, hypoglycemia and associated symptoms.

Nursing Mothers—Nadolol is excreted in human milk. Exercise caution when nadolol is administered to a nursing woman.

Pediatric Use—Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

Cardiovascular—Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System**—Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory**—Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal**—Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating, and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous**—Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision; infrequent reversible alopecia.

The following adverse reactions have been reported in patients taking nadolol and/or other beta-adrenergic blocking agents, but no causal relationship to nadolol has been established. **Central Nervous System**—reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal**—mesenteric arterial thrombosis; ischemic colitis; elevated liver enzymes. **Hematologic**—agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic**—fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous**—pemphigoid rash; hypertensive reaction in patients with pheochromocytoma; sleep disturbances; Peyronie's disease. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

OVERDOSAGE: Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

Excessive Bradycardia—Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure—Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

Hypotension—Administer vasopressors, e.g., epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm—Administer a $beta_2$-stimulating agent and/or a theophylline derivative.

DOSAGE—For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg qd; may be gradually increased in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 40 or 80 mg qd (doses up to 160 or 240 mg daily may be needed). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg qd; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 40 or 80 mg qd (doses up to 240 or 320 mg daily may be needed).

Patients with renal failure require adjustment in dosing interval; see package insert for dosage in these patients.

For full prescribing information consult package insert.

HOW SUPPLIED: In scored tablets containing 20, 40, 80, 120, or 160 mg nadolol per tablet in bottles of 100. The 40 mg, 80 mg, and 120 mg tablets are available in bottles of 1000 tablets. The 20 mg, 40 mg, and 80 mg tablets are also available in Unimatic® unit-dose packs of 100 tablets.

The Gold Standard in ultrasound now comes to Cardiology. The ACUSON® 128 Computed Sonography™ System. A complete Cardiovascular system utilizing our unique proprietary technology. A technology beyond phased array that provides the best image quality and the best Doppler all in one unit for both Cardiology and Vascular applications.

Nowhere else can you find all this:

- Gold Standard image quality.
- Fully simultaneous steerable continuous wave and pulsed Doppler at all velocity scales to increase diagnostic accuracy and confidence while reducing exam time.
- Dual frequency cardiac transducers that provide more exam flexibility without changing transducers.
- Optimum vascular imaging with linear format to provide the best field of view.
- Color Doppler Imaging option for both sector and linear applications.
- Guaranteed 99% up-time.

INTRODUCING THE GOLD STANDARD IN ULTRASOUND TO CARDIOLOGY.

THE ACUSON 128 COMPUTED SONOGRAPHY SYSTEM.

Call us to see the best in Cardiovascular imaging. The ACUSON 128 Computed Sonography System. 1-800-4-ACUSON or in California 1-800-5-ACUSON.

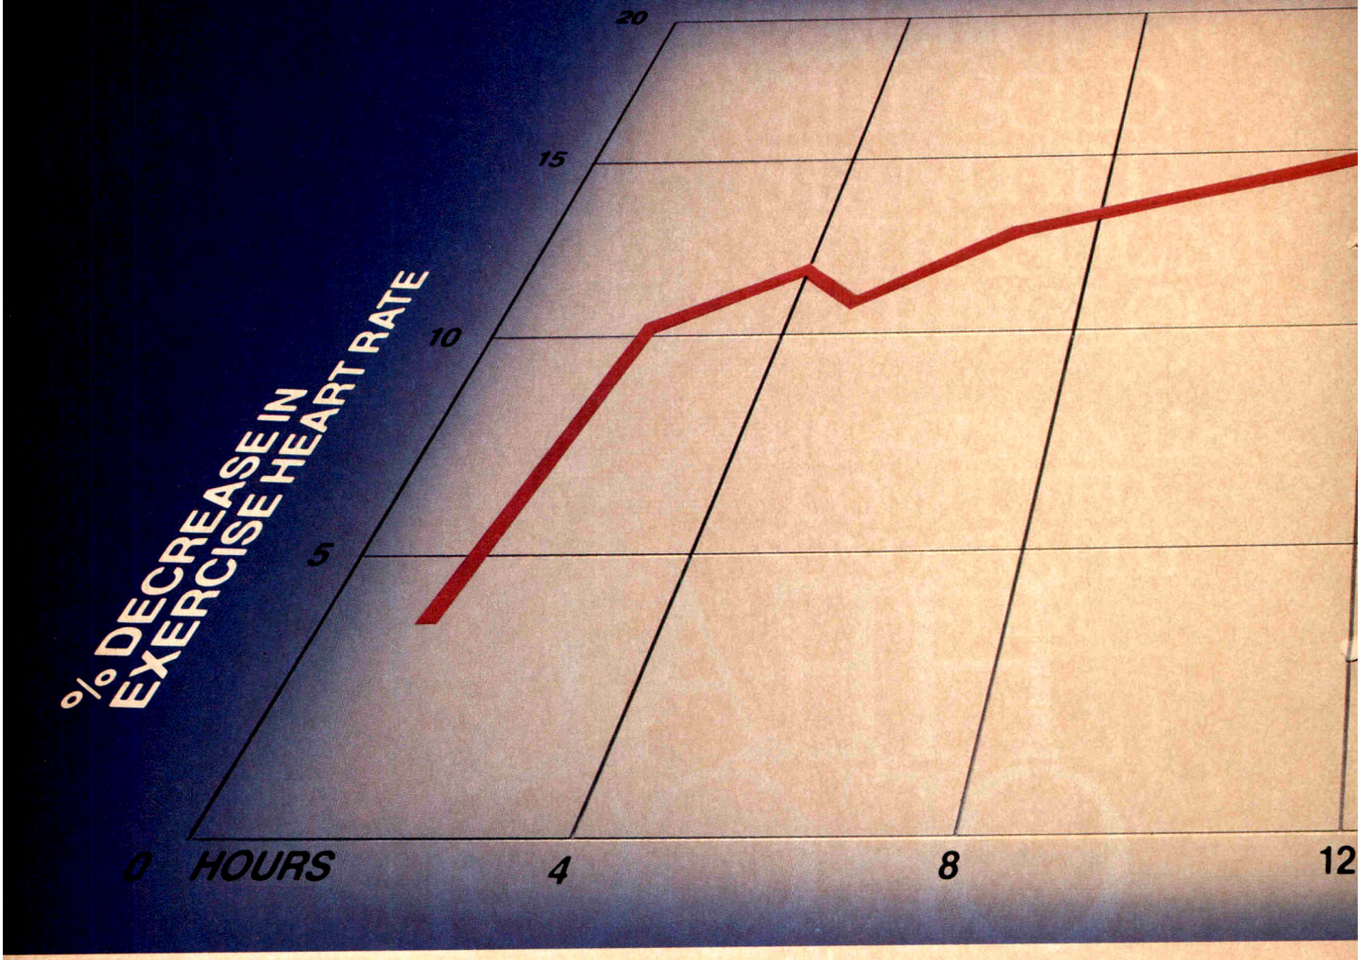
HEARTS OF GOLD.

We challenge angina to



INDERAL® LA holds the line all day against angina attacks.

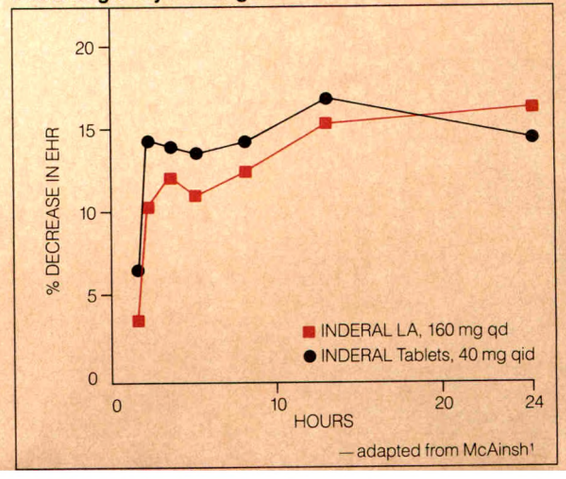
Smooth, sustained 24-hour beta blockade from a single daily dose

Periodic tests of exercise heart rate taken over 24 hours prove it. Once-daily INDERAL® LA sustains beta blockade night and day, just as well as the standard in anti-anginal therapy—qid INDERAL® (propranolol HCl) Tablets.[1]

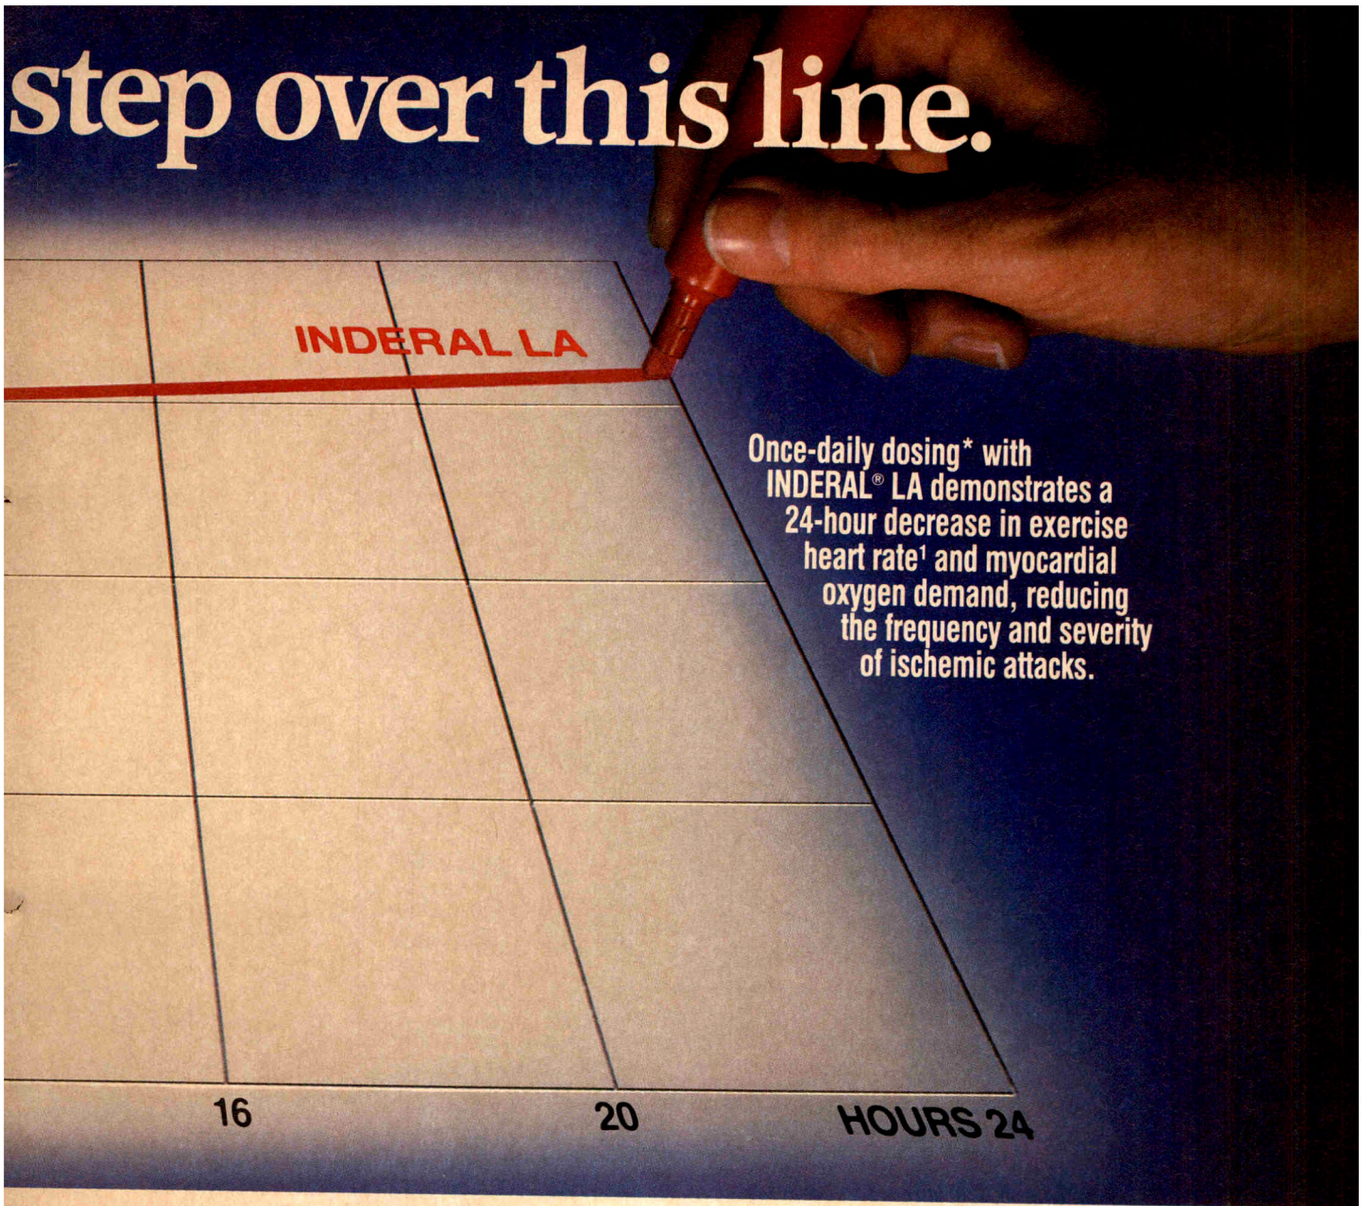
In fact, the graph demonstrates similar reductions in exercise heart rate when comparing controlled-release INDERAL® LA Capsules with divided-dose INDERAL (propranolol HCl) Tablets.[1]

The performance of INDERAL LA is also confirmed in clinical studies showing comparable reduction in the frequency and severity of angina attacks.[2,3]

Mean percentage decrease in exercise heart rate (EHR) with a single day's dosing in 12 volunteers.[1]



—adapted from McAinsh[1]



The logical complement to many other anti-anginals† in reducing symptomatic and silent ischemic episodes in unstable angina patients

As first-line therapy, INDERAL Tablets produce a favorable balance of hemodynamic effects in combination with nitrates and/or the calcium-channel blocker, nifedipine. It offsets the reflex tachycardia that concomitant vasodilator therapy can produce. Beyond that, in the presence of nitrates and nifedipine, it's been proven to reduce the number and duration of both symptomatic and silent ischemic episodes in unstable angina.[4]

Simplifying any anti-anginal regimen

Once-daily INDERAL LA helps keep a multi-drug, multi-dose, anti-anginal regimen as simple as possible. With INDERAL LA's control proven comparable to INDERAL Tablets, there's no need to postpone the convenience of once-daily dosing. *Start* your patients on INDERAL LA. And give them all the added benefits of therapy that's easy to tolerate and easy to remember to take.

ONCE-DAILY
INDERAL® LA
(PROPRANOLOL HCl) LONG ACTING CAPSULES

Holding the line all day against angina

Like conventional INDERAL Tablets, INDERAL LA should not be used in the presence of congestive heart failure, sinus bradycardia, cardiogenic shock, heart block greater than first degree, and bronchial asthma.

*When converting patients from INDERAL Tablets to INDERAL LA, start with the nearest milligram equivalent of INDERAL LA once daily. Evaluate clinical results to determine if dosage adjustment is necessary.
†The possibility of additive adverse cardiac effects mandates careful patient selection and close clinical monitoring. Please refer to respective package inserts for additional information.

Please see next page for brief summary of prescribing information.

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)*

INDERAL® LA brand of propranolol hydrochloride **(Long Acting Capsules)**

DESCRIPTION. INDERAL LA is formulated to provide a sustained release of propranolol hydrochloride. INDERAL LA is available as 60 mg, 80 mg, 120 mg, and 160 mg capsules.

CLINICAL PHARMACOLOGY. INDERAL is a nonselective, beta-adrenergic receptor-blocking agent possessing no other autonomic nervous system activity. It specifically competes with beta-adrenergic receptor-stimulating agents for available receptor sites. When access to beta-receptor sites is blocked by INDERAL, the chronotropic, inotropic, and vasodilator responses to beta-adrenergic stimulation are decreased proportionately.

INDERAL LA Capsules (60, 80, 120, and 160 mg) release propranolol HCl at a controlled and predictable rate. Peak blood levels following dosing with INDERAL LA occur at about 6 hours and the apparent plasma half-life is about 10 hours. When measured at steady state over a 24-hour period the areas under the propranolol plasma concentration-time curve (AUCs) for the capsules are approximately 60% to 65% of the AUCs for a comparable divided daily dose of INDERAL Tablets. The lower AUCs for the capsules are due to greater hepatic metabolism of propranolol, resulting from the slower rate of absorption of propranolol. Over a twenty-four (24) hour period, blood levels are fairly constant for about twelve (12) hours then decline exponentially.

INDERAL LA should not be considered a simple mg-for-mg substitute for conventional propranolol and the blood levels achieved do not match (are lower than) those of two to four times daily dosing with the same dose. When changing to INDERAL LA from conventional propranolol, a possible need for retitration upwards should be considered especially to maintain effectiveness at the end of the dosing interval. In most clinical settings, however, such as hypertension or angina where there is little correlation between plasma levels and clinical effect, INDERAL LA has been therapeutically equivalent to the same mg dose of conventional INDERAL as assessed by 24-hour effects on blood pressure and on 24-hour exercise responses of heart rate, systolic pressure, and rate pressure product. INDERAL LA can provide effective beta blockade for a 24-hour period.

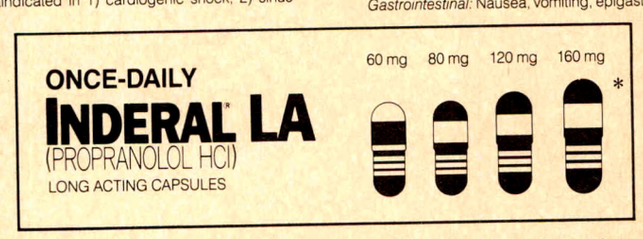
INDICATIONS AND USAGE. Hypertension: INDERAL LA is indicated in the management of hypertension; it may be used alone or used in combination with other antihypertensive agents, particularly a thiazide diuretic. INDERAL LA is not indicated in the management of hypertensive emergencies.

Angina Pectoris Due to Coronary Atherosclerosis: INDERAL LA is indicated for the long-term management of patients with angina pectoris.

Migraine: INDERAL LA is indicated for the prophylaxis of common migraine headache. The efficacy of propranolol in the treatment of a migraine attack that has started has not been established and propranolol is not indicated for such use.

Hypertrophic Subaortic Stenosis: INDERAL LA is useful in the management of hypertrophic subaortic stenosis, especially for treatment of exertional or other stress-induced angina, palpitations, and syncope. INDERAL LA also improves exercise performance. The effectiveness of propranolol hydrochloride in this disease appears to be due to a reduction of the elevated outflow pressure gradient which is exacerbated by beta-receptor stimulation. Clinical improvement may be temporary.

CONTRAINDICATIONS. INDERAL is contraindicated in 1) cardiogenic shock; 2) sinus bradycardia and greater than first-degree block; 3) bronchial asthma; 4) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL.



WARNINGS. CARDIAC FAILURE: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, if necessary, they can be used with close follow-up in patients with a history of failure who are well compensated and are receiving digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta blockers can, in some cases, lead to cardiac failure. Therefore, at the first sign or symptom of heart failure, the patient should be digitalized and/or treated with diuretics, and the response observed closely, or INDERAL should be discontinued (gradually, if possible).

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuance of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned, the dosage should be gradually reduced over at least a few weeks, and the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications.

Nonallergic Bronchospasm (eg, chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

MAJOR SURGERY: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

INDERAL (propranolol HCl), like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, eg, dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in starting and maintaining the heartbeat has also been reported with beta blockers.

DIABETES AND HYPOGLYCEMIA: Beta blockers should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected. Following insulin-induced hypoglycemia, propranolol may cause a delay in the recovery of blood glucose to normal levels.

THYROTOXICOSIS: Beta blockade may mask certain clinical signs of hyperthyroidism. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol may change thyroid function tests, increasing T_4 and reverse T_3, and decreasing T_3.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case, this resulted after an initial dose of 5 mg propranolol.

PRECAUTIONS. GENERAL: Propranolol should be used with caution in patients with impaired hepatic or renal function. INDERAL (propranolol HCl) is not indicated for the treatment of hypertensive emergencies.

Beta-adrenoreceptor blockade can cause reduction of intraocular pressure. Patients should be told that INDERAL may interfere with the glaucoma screening test. Withdrawal may lead to a return of increased intraocular pressure.

CLINICAL LABORATORY TESTS: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DRUG INTERACTIONS: Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL (propranolol HCl) is administered. The added catecholamine-blocking action may produce an excessive reduction of resting sympathetic nervous activity which may result in hypotension, marked bradycardia, vertigo, syncopal attacks, or orthostatic hypotension.

Caution should be exercised when patients receiving a beta blocker are administered a calcium-channel-blocking drug, especially intravenous verapamil, for both agents may depress myocardial contractility or atrioventricular conduction. On rare occasions, the concomitant intravenous use of a beta blocker and verapamil has resulted in serious adverse reactions, especially in patients with severe cardiomyopathy, congestive heart failure, or recent myocardial infarction.

Aluminum hydroxide gel greatly reduces intestinal absorption of propranolol.

Ethanol slows the rate of absorption of propranolol.

Phenytoin, phenobarbitone, and *rifampin* accelerate propranolol clearance.

Chlorpromazine, when used concomitantly with propranolol, results in increased plasma levels of both drugs.

Antipyrine and *lidocaine* have reduced clearance when used concomitantly with propranolol.

Thyroxine may result in a lower than expected T_3 concentration when used concomitantly with propranolol.

Cimetidine decreases the hepatic metabolism of propranolol, delaying elimination and increasing blood levels.

Theophylline clearance is reduced when used concomitantly with propranolol.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In 18-month studies in both rats and mice, employing doses up to 150 mg/kg/day, there was no evidence of significant drug-induced toxicity. There were no drug-related tumorigenic effects at any of the dosage levels. Reproductive studies in animals did not show any impairment of fertility that was attributable to the drug.

PREGNANCY: Pregnancy Category C. INDERAL has been shown to be embryotoxic in animal studies at doses about 10 times greater than the maximum recommended human dose. There are no adequate and well-controlled studies in pregnant women. INDERAL should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

NURSING MOTHERS: INDERAL is excreted in human milk. Caution should be exercised when INDERAL is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS. Most adverse effects have been mild and transient and have rarely required the withdrawal of therapy.

Cardiovascular: Bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; thrombocytopenic purpura; arterial insufficiency, usually of the Raynaud type.

Central Nervous System: Light-headedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; vivid dreams; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. For immediate formulations, fatigue, lethargy, and vivid dreams appear dose related.

Gastrointestinal: Nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: Pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory: Bronchospasm.

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Auto-Immune: In extremely rare instances, systemic lupus erythematosus has been reported.

Miscellaneous: Alopecia, LE-like reactions, psoriasiform rashes, dry eyes, male impotence, and Peyronie's disease have been reported rarely. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been associated with propranolol.

DOSAGE AND ADMINISTRATION. INDERAL LA provides propranolol hydrochloride in a sustained-release capsule for administration once daily. If patients are switched from INDERAL Tablets to INDERAL LA Capsules, care should be taken to assure that the desired therapeutic effect is maintained. INDERAL LA should not be considered a simple mg-for-mg substitute for INDERAL. INDERAL LA has different kinetics and produces lower blood levels. Retitration may be necessary, especially to maintain effectiveness at the end of the 24-hour dosing interval.

HYPERTENSION—*Dosage must be individualized.* The usual initial dosage is 80 mg INDERAL LA once daily, whether used alone or added to a diuretic. The dosage may be increased to 120 mg once daily or higher until adequate blood-pressure control is achieved. The usual maintenance dosage is 120 to 160 mg once daily. In some instances a dosage of 640 mg may be required. The time needed for full hypertensive response to a given dosage is variable and may range from a few days to several weeks.

ANGINA PECTORIS—*Dosage must be individualized.* Starting with 80 mg INDERAL LA once daily, dosage should be gradually increased at three- to seven-day intervals until optimal response is obtained. Although individual patients may respond at any dosage level, the average optimal dosage appears to be 160 mg once daily. In angina pectoris, the value and safety of dosage exceeding 320 mg per day have not been established.

If treatment is to be discontinued, reduce dosage gradually over a period of a few weeks (see WARNINGS).

MIGRAINE—*Dosage must be individualized.* The initial oral dose is 80 mg INDERAL LA once daily. The usual effective dose range is 160-240 mg once daily. The dosage may be increased gradually to achieve optimal migraine prophylaxis. If a satisfactory response is not obtained within four to six weeks after reaching the maximal dose, INDERAL LA therapy should be discontinued. It may be advisable to withdraw the drug gradually over a period of several weeks.

HYPERTROPHIC SUBAORTIC STENOSIS—80-160 mg INDERAL LA once daily.

PEDIATRIC DOSAGE—At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

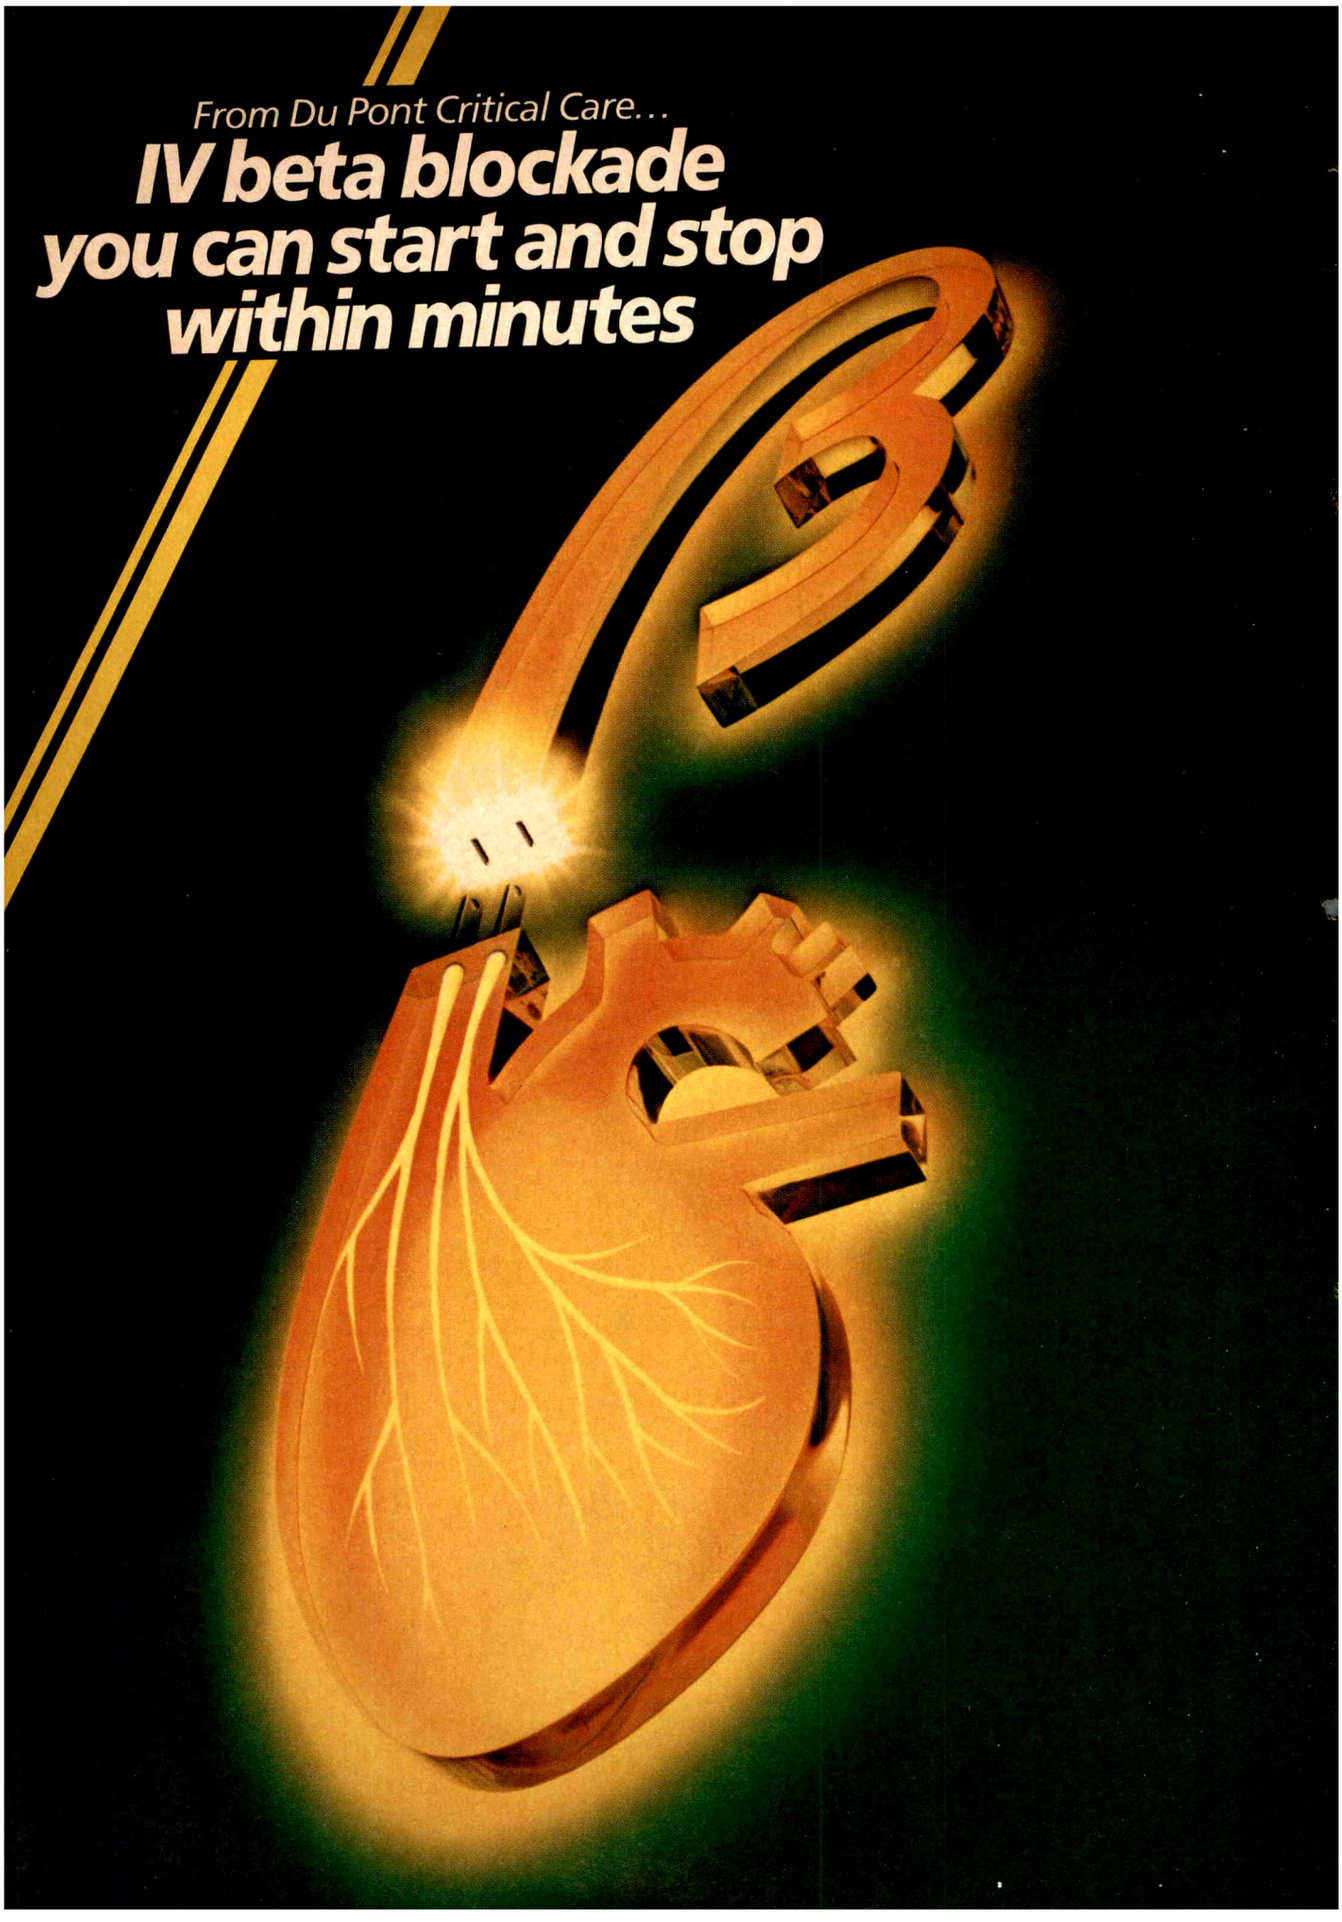
From Du Pont Critical Care...

IV beta blockade you can start and stop within minutes



For acute control of ventricular rate...

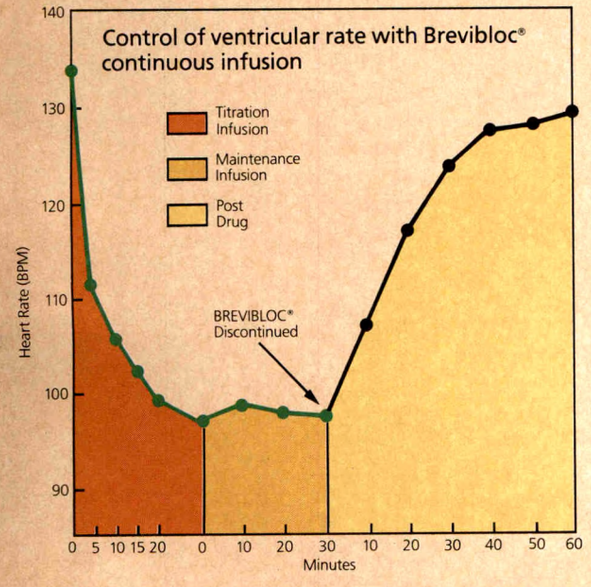
Brevibloc®
(esmolol HCl) INFUSION

Precise control

- Brevibloc® provides rapid, precise control of ventricular rate in atrial fibrillation or flutter, and in noncompensatory sinus tachycardia where, in the judgement of the physician, specific intervention is required

Rapid beta blockade, rapidly reversible

- Steady-state blood levels within 5 minutes with loading infusion [1]
- 9-minute elimination half-life allows substantial reversal of effects within 10-20 minutes of discontinuing infusion in the vast majority of patients[2-5]



Patients with atrial fibrillation/flutter titrated to dosage producing therapeutic response (50 to 300 mcg/kg/min) and continued at that dosage during maintenance period.

Adapted from Byrd RC, Sung RJ, Marks J, Parmley WW: *J Am Coll Cardiol* 1984;3(2):394.

Titratability improves control

- Administration *by continuous infusion* and 9-minute elimination half-life allow more accurate titration to meet fast-changing clinical requirements[5-8]

Safety enhanced by cardioselectivity

- Significantly less bronchospastic potential than propranolol[9]
- Unique pharmacokinetics and titratability make relative cardioselectivity clinically useful

Blood pressure reduction

- In patients with SVT, significant decreases in blood pressure occurred in 20-50% of patients. About 12% of SVT patients experienced symptomatic hypotension (mainly dizziness and diaphoresis)—6% of total discontinued[10]
- Patients—especially those with low pretreatment blood pressures—should be closely monitored during Brevibloc® administration

Please see references and brief summary of prescribing information on following page.

BREVIBLOC® INJECTION (esmolol hydrochloride) 10 mL Ampul—2.5 g

Brief Summary

NOT FOR DIRECT INTRAVENOUS INJECTION. BREVIBLOC® MUST BE DILUTED PRIOR TO ITS INFUSION (SEE DOSAGE AND ADMINISTRATION SECTION).

INDICATIONS AND USAGE

Supraventricular Tachycardia

BREVIBLOC® (esmolol HCl) is indicated for the rapid control of ventricular rate in patients with atrial fibrillation or atrial flutter in perioperative, postoperative, or other emergent circumstances where short term control of ventricular rate with a short-acting agent is desirable. BREVIBLOC® is also indicated in noncompensatory sinus tachycardia where, in the physician's judgement, the rapid heart rate requires specific intervention. BREVIBLOC® is not intended for use in chronic settings where transfer to another agent is anticipated.

CONTRAINDICATIONS

BREVIBLOC® (esmolol HCl) is contraindicated in patients with sinus bradycardia, heart block greater than first degree, cardiogenic shock or overt heart failure (see Warnings).

WARNINGS

Hypotension: In clinical trials 20-50% of patients treated with BREVIBLOC® (esmolol HCl) have had hypotension, generally defined as systolic pressure less than 90 mmHg and/or diastolic pressure less than 50 mmHg. About 12% of the patients have been symptomatic (mainly diaphoresis or dizziness). Hypotension can occur at any dose but is dose-related so that doses beyond 200 mcg/kg/min are not recommended. Patients should be closely monitored, especially if pretreatment blood pressure is low. Decrease of dose or termination of infusion reverses hypotension, usually within 30 minutes.

Cardiac Failure: Sympathetic stimulation is necessary in supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. Continued depression of the myocardium with beta blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, the dosage should be reduced or BREVIBLOC® should be withdrawn. Although this dosage adjustment or withdrawal may be sufficient because of the short elimination half-life of BREVIBLOC®, specific treatment may also be considered. (See Overdosage.)

Bronchospastic Diseases: PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative $beta_1$ selectivity and titratability, BREVIBLOC® may be used with caution in patients with bronchospastic diseases. However, since $beta_1$ selectivity is not absolute, BREVIBLOC® should be carefully titrated to obtain the lowest possible effective dose. In the event of bronchospasm, the infusion should be terminated immediately; a $beta_2$ stimulating agent may be administered if conditions warrant but should be used with particular caution as patients already have rapid ventricular rates.

Diabetes Mellitus and Hypoglycemia: BREVIBLOC® should be used with caution in diabetic patients requiring a beta-blocking agent. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected.

PRECAUTIONS

General

Infusion concentrations of 20 mg/mL were associated with more venous irritation and thrombophlebitis than concentrations of 10 mg/mL. Concentrations greater than 10 mg/mL should, therefore, be avoided.

Because the acid metabolite of BREVIBLOC® is primarily excreted unchanged by the kidney, BREVIBLOC® (esmolol HCl) should be administered with caution to patients with impaired renal function. The elimination half-life of the acid metabolite was prolonged ten-fold and the plasma level was considerably elevated in patients with end-stage renal disease.

Drug Interactions

Catecholamine-depleting drugs, e.g., reserpine, may have an additive effect when given with beta blocking agents. Patients treated concurrently with BREVIBLOC® and a catecholamine depletor should therefore be closely observed for evidence of hypotension or marked bradycardia, which may result in vertigo, syncope, or postural hypotension.

A study of interaction between BREVIBLOC® and warfarin showed that concomitant administration of BREVIBLOC® and warfarin does not alter warfarin plasma levels. BREVIBLOC® concentrations were equivocally higher when given with warfarin, but this is not likely to be clinically important.

When digoxin and BREVIBLOC® (esmolol HCl) were concomitantly administered intravenously to normal volunteers, there was a 10-20% increase in digoxin blood levels at some time points. Digoxin did not affect BREVIBLOC® pharmacokinetics. When intravenous morphine and BREVIBLOC® were concomitantly administered in normal subjects, no effect on morphine blood levels was seen, but BREVIBLOC® steady-state blood levels were increased by 46% in the presence of morphine. No other pharmacokinetic parameters were changed.

The effect of BREVIBLOC® on the duration of succinylcholine-induced neuromuscular blockade was studied in patients undergoing surgery. The onset of neuromuscular blockade by succinylcholine was unaffected by BREVIBLOC®, but the duration of neuromuscular blockade was prolonged from 5 minutes to 8 minutes. Although the interactions observed in these studies do not appear to be of major clinical importance, BREVIBLOC® should be titrated with caution in patients being treated concurrently with digoxin, morphine, succinylcholine or warfarin.

Carcinogenesis, Mutagenesis, Impairment of Fertility

Because of its short term usage no carcinogenicity, mutagenicity or reproductive performance studies have been conducted with BREVIBLOC®.

Pregnancy Category C

Teratogenicity studies in rats at intravenous dosages of BREVIBLOC® up to 3000 mcg/kg/min (ten times the maximum human maintenance dosage) for 30 minutes daily produced no evidence of maternal toxicity, embryotoxicity or teratogenicity, while a dosage of 10,000 mcg/kg/min produced maternal toxicity and lethality. In rabbits, intravenous dosages up to 1000 mcg/kg/min for 30 minutes daily produced no evidence of maternal toxicity, embryotoxicity or teratogenicity, while 2500 mcg/kg/min produced minimal maternal toxicity and increased fetal resorptions.

There are no adequate and well controlled studies in pregnant women. BREVIBLOC® should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers

It is not known whether BREVIBLOC® is excreted in human milk, however, caution should be exercised when BREVIBLOC® is administered to a nursing woman.

Pediatric Use

The safety and effectiveness of BREVIBLOC® in children have not been established.

ADVERSE REACTIONS

Supraventricular Tachycardia

The following adverse reaction rates are based on use of BREVIBLOC® (esmolol HCl) in almost 400 clinical trial patients with supraventricular tachycardia. In addition, over 600 patients have been exposed in clinical studies of other conditions. The most important adverse effect has been hypotension (see Warnings). Most adverse effects have been mild and transient.

Cardiovascular—Symptomatic hypotension (diaphoresis, dizziness) occurred in 12% of patients, and therapy was discontinued in about 11%, about half of whom were symptomatic. Asymptomatic hypotension occurred in about 25% of patients. Hypotension resolved during BREVIBLOC® infusion in 63% of these patients and within 30 minutes after discontinuation of infusion in 80% of the remaining patients. Diaphoresis accompanied hypotension in 10% of patients. Peripheral ischemia occurred in approximately 1% of patients. Pallor, flushing, bradycardia (heart rate less than 50 beats per minute), chest pain, syncope, pulmonary edema and heart block have each been reported in less than 1% of patients. In two patients without supraventricular tachycardia but with serious coronary artery disease (post inferior myocardial infarction or unstable angina), severe bradycardia/sinus pause/asystole has developed, reversible in both cases with discontinuation of treatment.

Central Nervous System—Dizziness has occurred in 3% of patients; somnolence in 3%, confusion, headache, and agitation in about 2%, and fatigue in about 1% of patients. Paresthesia, asthenia, depression, abnormal thinking, anxiety, anorexia, and lightheadedness were reported in less than 1% of patients. One brief (30 second) episode of grand mal seizure has been reported.

Respiratory—Bronchospasm, wheezing, dyspnea, nasal congestion, rhonchi, and rales have each been reported in less than 1% of patients.

Gastrointestinal—Nausea was reported in 7% of patients. Vomiting has occurred in about 1% of patients. Dyspepsia, constipation, dry mouth, and abdominal discomfort have each occurred in less than 1% of patients. Taste perversion has also been reported.

Skin (Infusion Site)—Infusion site reactions including inflammation and induration were reported in about 8% of patients. Edema, erythema, skin discoloration, and burning at the infusion site have each occurred in less than 1% of patients.

Miscellaneous—Each of the following has been reported in less than 1% of patients: Urinary retention, speech disorder, abnormal vision, midscapular pain, rigors, and fever.

OVERDOSAGE

Acute Toxicity

A single case of accidental overdosage with BREVIBLOC® (esmolol HCl) has occurred to date. A 5000 mcg/kg/min dose of BREVIBLOC® instead of the recommended 500 mcg/kg/min loading dose, was administered over one minute to a patient with atrial flutter. Immediately following the infusion, marked decreases in heart rate and blood pressure were observed and the patient became drowsy but could be aroused. The infusion rate of BREVIBLOC® was decreased to 5 mcg/kg/min and over the next eight minutes the patient's rhythm converted to normal sinus rhythm and the patient started feeling better. Hypotension persisted for a period of four minutes after decreasing the dosage of BREVIBLOC®. The drowsiness disappeared 15 minutes following discontinuation of BREVIBLOC®.

Because of its approximately 9-minute elimination half-life, the first step in the event of toxicity should be to discontinue BREVIBLOC® administration. Then, based on the pharmacologic actions, the following general measures should also be considered:

Bradycardia: Intravenous administration of atropine or another anticholinergic drug.

Bronchospasm: Intravenous administration of a $beta_2$ stimulating agent and/or a theophylline derivative.

Cardiac Failure: Intravenous administration of a diuretic and/or digitalis glycoside. In shock resulting from inadequate cardiac contractility, intravenous administration of dopamine, dobutamine, isoproterenol, or amrinone may be considered.

DOSAGE AND ADMINISTRATION

NOT FOR DIRECT INTRAVENOUS INJECTION. BREVIBLOC® IS A CONCENTRATED, POTENT DRUG WHICH MUST BE DILUTED PRIOR TO ITS INFUSION. BREVIBLOC® SHOULD NOT BE ADMIXED WITH SODIUM BICARBONATE. BREVIBLOC® SHOULD NOT BE MIXED WITH OTHER DRUGS PRIOR TO DILUTION IN A SUITABLE INTRAVENOUS FLUID.

Note: Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

Dilution: Aseptically remove 20 mL from a 500-mL bottle of one of the intravenous fluids (refer to full prescribing information for compatibility with commonly used intravenous fluids) and add the contents of two (2) ampuls of BREVIBLOC® (each containing 2.5 g esmolol hydrochloride). This yields a final concentration of 10 mg/mL. The diluted solution is stable for at least 24 hours at room temperature. Note: Concentrations of BREVIBLOC® greater than 10 mg/mL are likely to produce irritation on continued infusion (see Precautions). BREVIBLOC® has, however, been well tolerated when administered via a central vein.

Supraventricular Tachycardia

In the treatment of supraventricular tachycardia, responses to BREVIBLOC® usually (over 95%) occur within the range of 50 to 200 mcg/kg/min. The average effective dosage is approximately 100 mcg/kg/min although dosages as low as 25 mcg/kg/min have been adequate in some patients. Dosages as high as 300 mcg/kg/min have been used, but these provide little added effect and an increased rate of adverse effects, and are not recommended. Dosage of BREVIBLOC® in supraventricular tachycardia must be individualized by titration in which each step consists of a loading dosage followed by a maintenance dosage.

To initiate treatment of a patient with supraventricular tachycardia, administer a loading dosage infusion of 500 mcg/kg/min of BREVIBLOC® for one minute followed by a 4 min maintenance infusion of 50 mcg/kg/min. If an adequate therapeutic effect is not observed within five minutes, repeat the same loading dosage and follow with a maintenance infusion increased to 100 mcg/kg/min.

Continue titration procedure as above, repeating loading infusion (500 mcg/kg/min for 1 minute), increasing maintenance infusion by increments of 50 mcg/kg/min (for 4 minutes). As the desired heart rate or a safety end-point (e.g., lowered blood pressure) is approached, omit the loading infusion and reduce incremental dose in maintenance infusion from 50 mcg/kg/min to 25 mcg/kg/min or lower. Also, if desired, increase interval between titration steps from 5 to 10 minutes.

This specific dosage and administration regimen has not been studied intraoperatively and because of the time required for titration, may not be optimal for intraoperative use.

Maintenance dosages above 200 mcg/kg/min have not been shown to have significantly increased benefits, and the safety of dosages above 300 mcg/kg/min has not been studied.

In the event of an adverse reaction, the dosage of BREVIBLOC® may be reduced or discontinued. If a local infusion site reaction develops, an alternative infusion site should be used. The use of butterfly needles should be avoided.

Abrupt cessation of BREVIBLOC® in patients has not been reported to produce the withdrawal effects which may occur with abrupt withdrawal of beta-blockers following chronic use in coronary artery disease (CAD) patients. However, caution should still be used in abruptly discontinuing infusions of BREVIBLOC® in CAD patients.

After achieving an adequate control of the heart rate and a stable clinical status in patients with supraventricular tachycardia, transition to alternative antiarrhythmic agents such as propranolol, digoxin, or verapamil, may be accomplished.

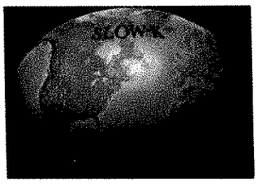
The World's Most Popular K

For good reasons

- ☐ **It works**—a 12-year record of efficacy[1]
- ☐ **It's safe**—unsurpassed by any other KCl tablet or capsule[2]*
- ☐ **It's acceptable vs liquids**—greater palatability, fewer GI complaints, lower incidence of nausea[2]
- ☐ **It's comparable to 10 mEq**—in low-dosage supplementation[3†]
- ☐ **It's economical**—less expensive than all other leading KCl slow-release supplements on a per tablet cost to the patient[1]



Slow-K®
potassium chloride
slow-release tablets 8 mEq (600 mg)

For patients who can't or won't tolerate liquid KCl.

*The most common adverse reactions to potassium salts are gastrointestinal side effects.

†Pooled mean serum potassium following oral administration of 30 mEq K-Tab compared to 24 mEq Slow-K in diuretic-treated hypertensives (n = 20) over 8 weeks.

Slow-Release Tablets
8 mEq (600 mg)

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION SEE PACKAGE INSERT)

INDICATIONS AND USAGE
BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.
1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy; and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS
Potassium supplements are contraindicated in patients with hyperkalemia, since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g., spironolactone, triamterene) (see OVERDOSAGE).

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation. Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to an enlarged left atrium.

WARNINGS
Hyperkalemia (See OVERDOSAGE).
In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic.

The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction With Potassium-Sparing Diuretics
Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal Lesions
Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains approximately one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic Acidosis
Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS
General:
The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium.

Information for Patients
Physicians should consider reminding the patient of the following:
To take each dose without crushing, chewing, or sucking the tablets.
To take this medicine only as directed. This is especially important if the patient is also taking both diuretics and digitalis preparations.
To check with the physician if there is trouble swallowing tablets or if the tablets seem to stick in the throat.
To check with the doctor at once if tarry stools or other evidence of gastrointestinal bleeding is noticed.

Laboratory Tests
Regular serum potassium determinations are recommended. In addition, during the treatment of potassium depletion, careful attention should be paid to acid-base balance, other serum electrolyte levels, the electrocardiogram, and the clinical status of the patient, particularly in the presence of cardiac disease, renal disease, or acidosis.

Drug Interactions
Potassium-sparing diuretics: see WARNINGS.

Carcinogenesis, Mutagenesis, Impairment of Fertility
Long-term carcinogenicity studies in animals have not been performed.

Pregnancy Category C
Animal reproduction studies have not been conducted with Slow-K. It is also not known whether Slow-K can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Slow-K should be given to a pregnant woman only if clearly needed.

Nursing Mothers
The normal potassium ion content of human milk is about 13 mEq/L. It is not known if Slow-K has an effect on this content. Caution should be exercised when Slow-K is administered to a nursing woman.

Pediatric Use
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
One of the most severe adverse effects is hyperkalemia (see CONTRAINDICATIONS, WARNINGS, and OVERDOSAGE). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration, and perforation (see CONTRAINDICATIONS and WARNINGS); other factors known to be associated with such conditions were present in many of these patients.

The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by taking the dose with meals or reducing the dose.

Skin rash has been reported rarely.

OVERDOSAGE
The administration of oral potassium salts to persons with normal excretory mechanisms for potassium rarely causes serious hyperkalemia. However, if excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, potentially fatal hyperkalemia can result (see CONTRAINDICATIONS and WARNINGS). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by an increased serum potassium concentration (6.5-8.0 mEq/L) and characteristic electrocardiographic changes (peaking of T waves, loss of P wave, depression of S-T segment, and prolongation of the Q-T interval). Late manifestations include muscle paralysis and cardiovascular collapse from cardiac arrest (9-12 mEq/L).

Treatment measures for hyperkalemia include the following: (1) elimination of foods and medications containing potassium and of potassium-sparing diuretics; (2) intravenous administration of 300-500 ml/hr of 10% dextrose solution containing 10-20 units of insulin per 1,000 ml; (3) correction of acidosis, if present, with intravenous sodium bicarbonate; (4) use of exchange resins, hemodialysis, or peritoneal dialysis.

In treating hyperkalemia in patients who have been stabilized on digitalis, too rapid a lowering of the serum potassium concentration can produce digitalis toxicity.

DOSAGE AND ADMINISTRATION
The usual dietary intake of potassium by the average adult is 40-80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires the loss of 200 or more mEq of potassium from the total body store. Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for the prevention of hypokalemia to 40-100 mEq or more per day for the treatment of potassium depletion. Large numbers of tablets should be given in divided doses.

Note: Slow-K slow-release tablets must be swallowed whole and never crushed, chewed, or sucked.

HOW SUPPLIED
Tablets—600 mg of potassium chloride (equivalent to 8 mEq) round, buff colored, sugar-coated (imprinted Slow-K)

Bottles of 100	NDC 0083-0165-30
Bottles of 1000	NDC 0083-0165-40
Consumer Pack—One Unit	
12 Bottles—100 tablets each	NDC 0083-0165-65
Accu-Pak® Unit Dose (Blister pack)	
Box of 100 (strips of 10)	NDC 0083-0165-32

Do not store above 86°F (30°C). Protect from moisture. Protect from light.

Dispense in tight, light-resistant container (USP).

A Symposium: Advances in Clinical Practice of Nitrate Therapy

Introduction

ADAM SCHNEEWEISS, MD, and MARIJA WEISS, DSc

About 10 years ago it was believed that only little more might be said on nitrate therapy. After 100 years of use, nitrates appeared to offer many well-known therapeutic advantages, but no lines for further research. Over the last decade, however, we have observed the following new and exciting developments in the field, which change the profile of nitrate therapy and provide new and important therapeutic tools:

1. New indications for nitrates, including prevention (preferable to treatment) of all forms of angina pectoris and silent ischemia, treatment of myocardial infarction, congestive heart failure, perioperative cardiovascular complications and various extracardiac indications.

From Schwarz GmbH, Monheim, Federal Republic of Germany.

2. Development of molecules with relative selectivity to various segments of the circulation, such as isosorbide-5-mononitrate, which appears to be relatively selective for the venous circulation.

3. Development of new drug delivery systems. Isosorbide dinitrate spray and nitroglycerin spray were shown to be superior to sublingual tablets in rapidity of effect in treatment of angina pectoris, pulmonary edema and congestive heart failure. Transdermal nitroglycerin patches allow long-term treatment of congestive heart failure and angina pectoris. Long-acting oral formulations of nitrates simplify some traditional and complex therapeutic regimens.

This symposium on advances in the clinical practice of nitrate therapy will discuss some of these achievements.

More Rapid Relief of Pain with Isosorbide Dinitrate Oral Spray than with Sublingual Tablets in Elderly Patients with Angina Pectoris

LEONARDO H. REISIN, MD, ELIAHU LANDAU, MD, and AZIZ DARAWSHI, MD

To evaluate the possibility of improving clinical practice in the treatment of angina pectoris, the duration of relief of pain with isosorbide dinitrate (ISDN) oral spray and sublingual tablets were compared in elderly patients with chronic stable angina pectoris. Nine patients (mean age 67 years) were studied in a randomized crossover trial. The patients underwent bicycle ergometry, which resulted in typical chest pain associated with electrocardiographic ST-segment depression in all 9. The patients received ISDN oral spray or sublingual tablets immediately on termination of exercise. At least 6 hours later another ergometry test was performed and the patients were crossed over to the other drug. ISDN spray relieved pain in all patients at a mean duration of 61.6 ± 24.4 seconds after administration, whereas the duration of relief of pain by ISDN sublingual tablets was 112.4 ± 70 seconds. The difference was highly significant ($p < 0.0005$). It is concluded that clinical practice of treatment of angina pectoris in the elderly can be improved by using ISDN oral spray rather than sublingual tablets. The spray is effective at twice the rapidity of the sublingual tablet. (Am J Cardiol 1988;61:2E–3E)

Nitrates are used for relief and prevention of pain in patients with angina pectoris.[1–4] The most rapid conventional therapy for relief of pain in patients with exercise-induced angina pectoris is sublingual administration of nitrates in tablet form. The rapidity of action is important because until relief, the patients have myocardial ischemia as seen by electrocardiographic ST-segment depression. However, even the rapidly acting sublingual tablets take a few minutes before onset of effect. Peak plasma levels of nitrates are achieved about 2 minutes after dissolution of the tablet.[5] Moreover, the time required for dissolution of the tablet (which varies from patient to patient) further delays the onset of action. In elderly patients this delay may be more pronounced because dryness of the mouth (more often a problem in the elderly than in the young) impairs tablet dissolution.[6]

Isosorbide dinitrate (ISDN) oral spray theoretically should act more rapidly than sublingual tablets because no time is required for dissolution of a tablet. In this study we compared the rapidity of pain relief by ISDN oral spray and sublingual tablets in the elderly.

From the Cardiology Department, Barzilai Hospital, Ashkelon, Israel.

Address for reprints: Adam Schneeweiss, MD, Geriatric Cardiology Research Foundation, 9 Kehilat Sofia Street, 69018 Tel Aviv, Israel.

Methods

Nine patients (8 men and 1 woman, mean age 67 ± 4.6 years) with coronary artery disease and exercise-induced chronic stable angina pectoris were studied. Four had old myocardial infarction. No patient had undergone coronary artery bypass surgery. None had clinical or radiographic evidence of congestive heart failure. They did not receive any cardioactive drug for at least 3 days before the study. Each patient signed an informed consent.

The patients underwent 2 bicycle exercise tests, 1 with each formulation of the drug. A 12-lead electrocardiogram was constantly monitored on an oscilloscope and a hard-copy recording was performed every minute throughout the study and during recovery. Exercise was terminated upon development of chest pain similar to that of the anginal episodes that the patients have been having, associated with electrocardiographic ST-segment depression of at least 1 mm. Immediately after termination of exercise the patients received either 1 squirt of ISDN oral spray (Isoket® spray, Schwarz GmbH), equal to 1.25 mg of ISDN, or a sublingual tablet of 5 mg of ISDN. Time to disappearance

of pain was recorded. A similar study was repeated after at least 6 hours, and the patients were crossed over to the other formulation of ISDN.

Results

All patients had chest pain associated with ST-segment depression. Administration of ISDN in both formulations resulted in relief of pain and electrocardiographic changes in all patients. Sublingual ISDN tablets relieved pain within 112.4 ± 67 seconds and oral spray within 61.6 ± 24.4 seconds. The difference was highly significant ($p < 0.0005$). Both formulations were comparably well tolerated. No adverse effects except for mild headaches were observed.

Discussion

We found that ISDN oral spray relieved chest pain twice as rapidly as sublingual tablets (of a higher dose) in elderly patients with chronic stable exercise-induced angina pectoris.

Although sublingual tablet administration is considered the most rapid conventional method for relief of pain in angina pectoris, its effect is not immediate and it has certain limitations. When administered sublingually as tablets, nitrates reach peak plasma levels at least 2 minutes after dissolution of the tablet.[5] However, the time required for dissolution of the tablet varies from patient to patient. Because it takes at least 1 minute, it increases time to peak plasma level by at least 50%.

The time required for the tablet to dissolve depends on various factors and may be prolonged in patients with dry mouth and in those living in a hot climate. Relative dryness of the mouth is more common in elderly than in younger patients, and such patients may require longer periods for dissolution of sublingual tablets.[6] Moreover, elderly distressed patients, mainly those in whom chest pain is associated with dyspnea and tachypnea, find it difficult to hold the tablet under their tongue. In dependent elderly patients the nurse has to follow the patients for several minutes until the tablet dissolves. The use of ISDN oral spray solves all these problems.

Our findings are compatible with those of a pharmacokinetic study, which showed that therapeutic plasma levels of ISDN are achieved several minutes earlier with spray than with sublingual tablets.[7]

The rapidity of action of nitrate oral spray can be clearly demonstrated by hemodynamic evaluation. Kimchi et al[8] reported that hemodynamic effects of nitroglycerin oral spray were evident within 2 minutes in patients with angina pectoris (younger than patients studied by us). We have observed hemodynamic improvement with ISDN spray within 1 minute in patients with pulmonary edema studied with a Swan-Ganz catheter (unpublished data).

The specific oral spray used in this study has a special advantage in the elderly in that it does not require inhalation. Elderly patients may find it difficult to synchronize the administration of spray and rate of breathing.

In summary, ISDN oral spray effectively and rapidly relieves chest pain in patients with angina pectoris. In elderly patients it was shown to act more rapidly than sublingual tablets. It can improve the clinical practice of treatment of angina pectoris.

Increased Exercise Tolerance and Reduced Duration of Ischemia After Isosorbide Dinitrate Oral Spray in Angina Pectoris

ALAN MARMOR, MD, MICHAEL PLICH, MD, DAVID BLONDHEIM, MD, TALI SHARIR, MD, and JOSEPH S. ALPERT, MD

The prophylactic and therapeutic anti-ischemic efficacy of isosorbide dinitrate (ISDN) oral spray was assessed in 10 patients with coronary artery disease and stable angina pectoris. The patients entered a randomized crossover study of ISDN spray and placebo, involving bicycle exercise testing. Each patient underwent 2 exercise tests at least 4 hours apart. Immediately before initiation of exercise they received either ISDN spray or placebo and crossed over during the other test. ISDN spray delayed the onset of anginal pain by about 40%, from a mean of 5.1 ± 1.4 minutes with placebo to 7.2 ± 1.3 minutes with the active drug ($p < 0.001$). Time of onset of ST-segment depression was also significantly prolonged, from 7.1 ± 1.5 minutes with placebo to 10.2 ± 1.2 minutes with ISDN ($p < 0.001$). The patients achieved a higher double product at onset of pain with ISDN than with placebo. The drug also reduced the time of disappearance of pain after discontinuation of exercise from 3.2 ± 0.7 to 2.1 ± 0.8 minutes ($p < 0.001$), and the time of disappearance of electrocardiographic changes from 4.2 ± 0.6 to 2.5 ± 0.8 minutes ($p < 0.005$). These findings indicate that oral ISDN spray is an effective prophylactic for exercise-induced angina. Its rapid onset of action makes it especially suitable for usage immediately before exercise.

(Am J Cardiol 1988;61:4E–6E)

Isosorbide dinitrate (ISDN) is widely used for the treatment (sublingual tablets) and prevention (oral tablets and transdermal delivery systems) of attacks of angina pectoris. Even the most rapid method of administration, sublingual tablets, takes at least 2 minutes until the onset of effect. Usually this takes some more time because 2 minutes are the required time for nitrates administered in sublingual tablet form to reach peak plasma levels.[1] However, an additional period is required for dissolution of the tablet, which has to take place, at least partially, before absorption begins. This period shows interpatient variability and further delays onset of action.

It is a common practice to administer nitrates in the form of sublingual tablets before effort that is known to cause chest pain in patients with angina pectoris. Because of the reasons discussed, the onset of this effect takes several minutes. Although this is usually sufficient for most patients with angina pectoris, a more rapid method of administration is desirable.

We assessed the antianginal efficacy of ISDN spray (Isoket® spray, Schwartz GmbH) in patients with exercise-induced angina pectoris in order to determine and quantitate its time course.

Methods

Patients: Ten patients (6 men and 4 women), aged 49 to 68 years (mean 58.9 ± 6.2) were included in the study. All patients had chronic stable angina pectoris with positive exercise test results (exercise-induced angina associated with ischemic ST-segment depression of 1.5 mm or more, lasting at least 0.08 second) and angiographically proved coronary artery disease. Five patients have had a myocardial infarction at least 4 months before the study. No patient had undergone coronary artery bypass surgery. No patient had evidence of congestive heart failure or systemic or pulmonary hypertension. Before the study, all patients were

Address for reprints: Alan Marmor, MD, Department of Cardiology, Rebeca Ziev Medical Center, Safad, Israel.

known to tolerate sublingual nitroglycerin or ISDN, or both.

Isosorbide dinitrate oral spray: The ISDN spray is a watery solution enclosed in a metal aerosol container and provides 1.25 mg ISDN in each squirt of Isoket. Inhalation of the drug is not required and it is administered on the lingual and other oral mucosa.

Protocol: In the morning of the study all patients underwent physical examination and electrocardiography at rest. The patients were then prepared for exercise testing. Immediately before the initiation of exercise, they received in a randomized single-blind order, either 1 squirt of placebo or of ISDN sprayed on the tongue. Exercise testing was performed according to a 3-minute-stage protocol, starting with 25 W and increasing the load by this extent every 3 minutes. The endpoint of the study was chest pain, similar to that experienced by the patient during effort. The patients were instructed to inform the investigator immediately of onset of chest pain, of chest pain comparable to that experienced during effort before the study and of the time at which chest pain completely subsided after termination of exercise.

All cardioactive drugs were withdrawn before the study. Beta blockers were discontinued 7 days before the study and calcium antagonists 2 days before. In these last 2 days only sublingual nitrates were used, if required. During exercise and recovery a 12-lead electrocardiogram was recorded every 30 seconds and electrocardiographic leads 1, aVF and V_5 were constantly monitored. Heart rate and blood pressure were recorded in the sitting position before, every minute during and at termination of exercise, and during the recovery period. Time to onset of angina and to appearance of 1.0 mm of ST-segment depression lasting at least 0.08 second, and time of disappearance of pain and of ST-segment depression after discontinuation of exercise were measured. The paired *t* test was used for statistical analysis.

Results

Effect on ischemia: ISDN spray delayed the onset of angina and electrocardiographic ischemic changes in all patients. Exercise time to pain was 5.1 ± 1.4 minutes with placebo and 7.2 ± 1.3 minutes with ISDN ($p < 0.001$). Time to appearance of ST-segment depression was 7.1 ± 1.5 minutes with placebo and 10.2 ± 1.2 minutes with ISDN. Time of disappearance of pain after discontinuation of exercise was shortened from 3.2 ± 0.8 minutes with placebo to 2.1 ± 0.8 minutes with ISDN ($p < 0.001$). Time to disappearance of ST-segment depression was shortened from 4.2 ± 0.6 to 2.5 ± 0.8 minutes, respectively ($p < 0.005$).

Hemodynamic effects: Heart rate and systolic and diastolic blood pressure before exercise were not significantly different before the trial with placebo and with ISDN. At termination of exercise, systolic blood pressure increased from 163.5 ± 17.3 mm Hg with placebo to 192.5 ± 15.7 mm Hg with ISDN ($p < 0.001$). Diastolic blood pressure was not significantly different. Heart rate was 129.5 ± 16.8 beats/min with placebo and 142.5 ± 11.2 with ISDN ($p < 0.001$). Double product increased from 21,370 ± 4,613 to 27,535 ± 32,800 ($p < 0.001$).

Adverse effects: Two patients had transient headaches and 1 patient had transient dizziness with a slight decrease in blood pressure after ISDN. All patients completed the study without having major adverse effects.

Discussion

Our previous experience with ISDN spray suggests that because of its rapid action, it may be superior to sublingual nitrate tablets. Previously, we observed that ISDN spray exerts a beneficial hemodynamic effect within less than 30 seconds in patients with acute pulmonary edema and that the spray relieves exercise-induced chest pain and electrocardiographic changes 30 to 50% more rapidly than sublingual tablets of ISDN. The onset of effect is more rapid with ISDN spray than with intravenous infusion. This is not only because of the time required to start an intravenous line but also because of first-pass metabolism of nitrates in the liver, which is avoided when oral spray is used.[2,3] Therefore, this formulation was chosen for evaluation as pre-effort therapy in patients with exercise-induced angina pectoris. Because of the rapid onset of action, the spray is especially suitable for use immediately before initiation of exercise and the patient does not have to wait until dissolution of a tablet.

The present study revealed that ISDN spray, administered immediately before the initiation of exercise, increased exercise tolerance in patients with chronic stable angina pectoris. The drug increased exercise duration by about 40%. This finding is comparable to results achieved with sublingual nitroglycerin tablets[4–7] and nitroglycerin oral spray.[8] This increase was associated with the usual cardiocirculatory effects of nitrates. ISDN also did not significantly lower diastolic blood pressure. When considerable autoregulatory coronary dilation has been achieved, as may be expected in patients with coronary artery disease who exercised to myocardial ischemia, myocardial flow distal to a fixed coronary stenosis has been shown to be directly related to perfusion pressure.[9,10] In the presence of peripheral vasodilation accompanying exercise, a vasodilator that excessively lowers diastolic blood pressure may impair coronary perfusion. As ISDN reduces left ventricular filling pressure, myocardial flow may increase in relation to a given perfusion pressure.

ISDN also significantly shortened the duration of chest pain and ST-segment depression. The effect of ISDN spray given as a prophylaxis immediately before exercise is equivalent to the effects achieved by nitrates administered at the onset of pain.

Kimchi et al[8] showed that nitroglycerin oral spray is an effective prophylactic for exercise-induced angina pectoris. The drug delayed or abolished the appearance of chest pain and ST-segment depression. The patients achieved a higher heart rate at peak exercise with nitroglycerin spray, associated with a decline in

the maximal exercise-induced ST-segment depression. Our results with ISDN are in accordance with those effects of nitroglycerin. However, ISDN has a longer half-life than nitroglycerin.[11,12] Therefore, it should be theoretically superior in its duration of action. ISDN spray, which combines both very rapid onset of action and relatively prolonged efficacy, has advantages as a prophylactic before exercise in patients with chronic stable angina pectoris. Another difference between the studies is that Kimchi et al[8] gave the drug 2 minutes before initiation of exercise. This early administration is required for sublingual tablets but, in our opinion, not necessary for the spray. The rapidity of action of the spray allows administration immediately at the initiation of exercise, as we did in this study. The spray has another theoretical advantage over tablets: The active drug is protected in the container while the tablets are repeatedly exposed when the bottle is opened. This may result in chemical degradation of the tablets.

In summary, ISDN spray is an effective prophylactic agent for use before initiation of exercise in patients with chronic stable angina pectoris. It not only increases the duration of exercise and delays the onset of pain and ischemic electrocardiographic changes but also shortens the duration of the ischemia when it does develop.

Nitroglycerin Oral Spray: Evaluation of Its Coronary Artery Dilative Action by Quantitative Angiography

KURT F. BACHMANN, MD, and ROLF E. GANSSER, MD

Twenty patients were studied angiographically before and after administration of glyceryl trinitrate (NTG) spray at a single oral dose of 0.8 mg in either a hydrosoluble (NTG-h) or liposoluble (NTG-l) solution. The assessment was by a randomized double-blind trial involving quantitative coronary angiography and pharmacologic stress testing using ergonovine maleate. The peak effect and duration of NTG-induced coronary dilatation were evaluated in 2 groups of 10 patients each, in whom NTG oral spray was given either under resting conditions (group A) or for the release of ergonovine-increased coronary vasomotor tone (group B). The study demonstrates that the 2 different galenic formulations of NTG spray are equally efficacious in dilating the conductance coronary arteries under both conditions.

When NTG-h and NTG-l oral spray were given subsequent to ergonovine-testing, the diameters of extramural coronary arteries are not only reset to their dimensions at baseline but furthermore increase above resting values by 15.1% and 15.5%, respectively. Ergonovine-induced coronary vasoconstriction was released significantly for a period of at least 30 minutes. Both the NTG-h and NTG-l oral spray are potent coronary vasodilators in patients with increased coronary vasomotor tone.

(Am J Cardiol 1988;61:7E–11E)

The downfall of organic nitrates in the long-term therapy of stable angina pectoris in the early 1970s[1] was followed by a decade of its recovery due to the development of long-acting nitrates such as isosorbide dinitrate and its metabolite isosorbide-5-mononitrate. Nevertheless, glyceryl trinitrate (NTG) has remained the "emergency nitrate" for the relief not only of anginal attacks but also for hemodynamic unloading in acute congestive heart failure, acute pulmonary hypertension and valvular insufficiency.

Hemodynamic unloading with a reduction of preload and afterload is considered to be the main beneficial effect of NTG in the relief of myocardial ischemia and in the improvement of depressed left ventricular performance.[2] Furthermore dilatation of coronary stenoses has been documented as a major component of the drug response.[3]

NTG is currently available in different galenic formulations for sublingual (tablet and capsule), transdermal (patch and ointment), parenteral and even rectal (rectal uvula) application. NTG aerosol spray for oral use has been available in West Germany for several years and has been studied with regard to improvement in exercise tolerance[4] and hemodynamic responses.[5–7] However, up to the present, the acute coronary dilative effect of NTG has been evaluated by quantitative coronary angiography in patients under resting conditions only.[3,8–10]

We evaluated the coronary dilative properties of a new hydrosoluble NTG lingual spray in patients with stable, exercise-induced angina pectoris and in patients with atypical chest pain during diagnostic ergonovine-provocation.

Methods

Nitroglycerin spray: A spray aerosol contains holds 10 ml of NTG solution and delivers about 2 doses at 0.4 mg at each spray. The standard spray contains NTG in aromatized liposoluble formulation (NTG-l), and the test spray in hydrosoluble formulation (NTG-h). In this study, spray containers looking identical in shape, size and color were used holding either NTG-l or NTG-h.

Patients: Two groups of 10 patients each were studied. Group A included 10 patients (9 men and 1 woman, ranging in age from 39 to 77 years [mean 56]) with stable exertional angina pectoris, a positive result on exercise testing and a more than 75% diameter stenosis in at least 1 major coronary artery.

From the Med. Klinik II und Poliklinik (Cardiology) University of Erlangen-Nuernberg, Federal Republic of Germany.

Address for reprints: Prof. Dr. med. K. Bachmann, Med. Klinik II und Poliklinik (Cardiology), Universitaet Erlangen-Nuernberg, Oestl. Stadtmauerstr. 29, D-8520 Erlangen, Federal Republic of Germany.

Group B consisted of 10 patients (5 men and 5 women, ranging in age from 54 to 66 years [mean 60]). All patients had a nonexertional, atypical form of chest pain and a negative exercise stress test result. Coronary angiograms demonstrated in 3 of these patients a coronary diameter narrowing between 51% and 75% in at least 1 major coronary artery. Two patients had a stenosis of less than 50% diameter reduction in 1 major coronary artery, 4 patients had angiographically normal coronary arteries, and 1 patient had a myocardial bridging of the left anterior descending coronary artery.

Informed consent was obtained from all patients before the invasive investigations. Long-acting nitrates, β-blocking drugs and calcium antagonists were discontinued 24 hours before the study.

Study protocol: The investigation consisted of a double-blind trial during which patients received either NTG-h or NTG-l oral spray in random fashion. Keeping the container vertical, NTG spray was administered orally at a total dose of 0.8 mg within 2 seconds, delivered per 2 metered doses of 0.4 mg each. A Sones catheter was placed across the brachial artery into the aortic root; after a 30-minute period of rest, baseline coronary angiograms were recorded. In group A, NTG spray was given after baseline coronary angiography and in group B, after angiographic controls following ergonovine provocation. Ergonovine testing was performed by sequential intravenous bolus injections of 0.1, 0.2 and 0.4 mg ergonovine maleate at 5-minute intervals. Three minutes after the last ergonovine bolus injection, coronary angiograms were recorded again to assess coronary vasoconstriction. Throughout this study, continuous electrocardiographic monitoring was performed and blood pressure in the pulmonary artery and the aorta was maintained.

Quantitative coronary angiography: Coronary angiography was repeated at intervals of 6, 15 and 30 minutes after the administration of NTG spray. Care was taken that within an individual patient the rotation of skew angles, height and magnification factors of the image intensifier were not altered during the study. Coronary angiograms with a spatial resolution of 4.5 LP/mm were obtained by using a high-resolution 7-inch image intensifier, a 35-mm cine technique with 25 frames/s and Omnipaque 300® (Schering) as contrast material. Frames filmed in end-diastole were selected for quantitative analyses at each condition.

Quantitative coronary analyses were performed with the computer-based Coronary-Angiography-Analysis-System.[11] The systems variability of repeated analyses in absolute dimension is less than 0.1 mm.[11] Coronary diameters were measured using automated contour detection and correction of pincushion distortion. The tip of the Sones catheter was placed into the ostium of a coronary artery and used as a scaling device for conversion of units in millimeters. In each individual patient coronary diameters were measured in angiographically normal, proximal segments of the left anterior descending, left circumflex and right coronary arteries. Thus, results are based on the measurements of 30 coronary segments in group A and in group

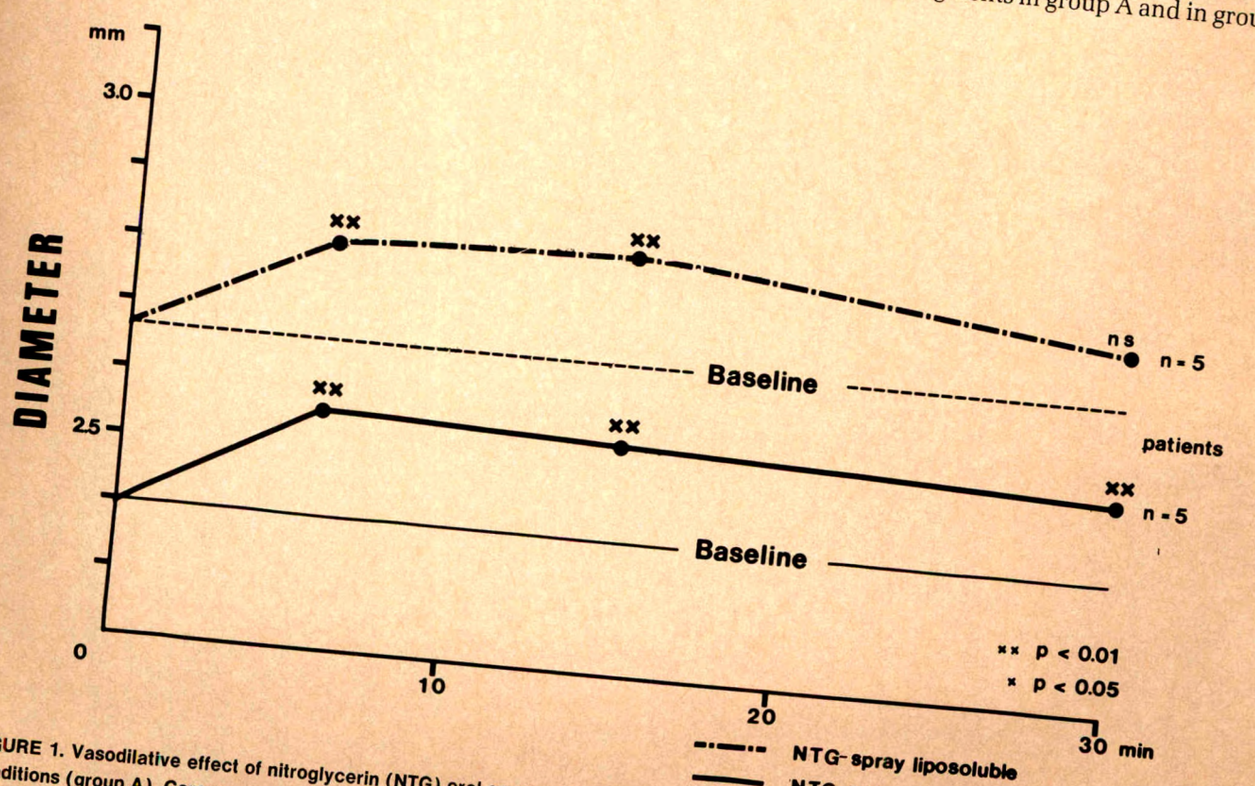

FIGURE 1. Vasodilative effect of nitroglycerin (NTG) oral spray on the diameter of coronary conductive vessels in patterns under resting conditions (group A). Coronary diameters are expressed as mean ± standard deviation out of 15 coronary segments for each NTG spray. ns = not significant.

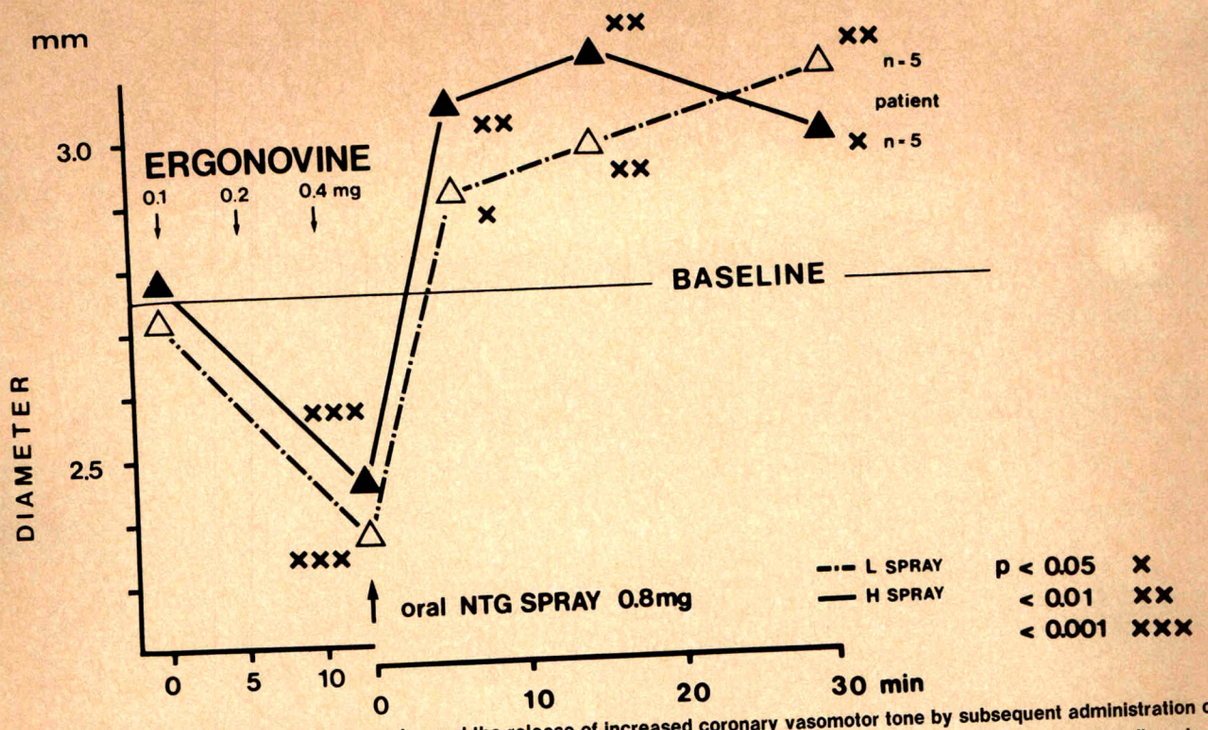

FIGURE 2. Vasoconstrictive effect of ergonovine and the release of increased coronary vasomotor tone by subsequent administration of nitroglycerin (NTG) oral spray. NTG is efficacious in releasing ergonovine-induced vasoconstriction with increasing coronary diameters above baseline values. H = hydrosoluble; L = liposoluble.

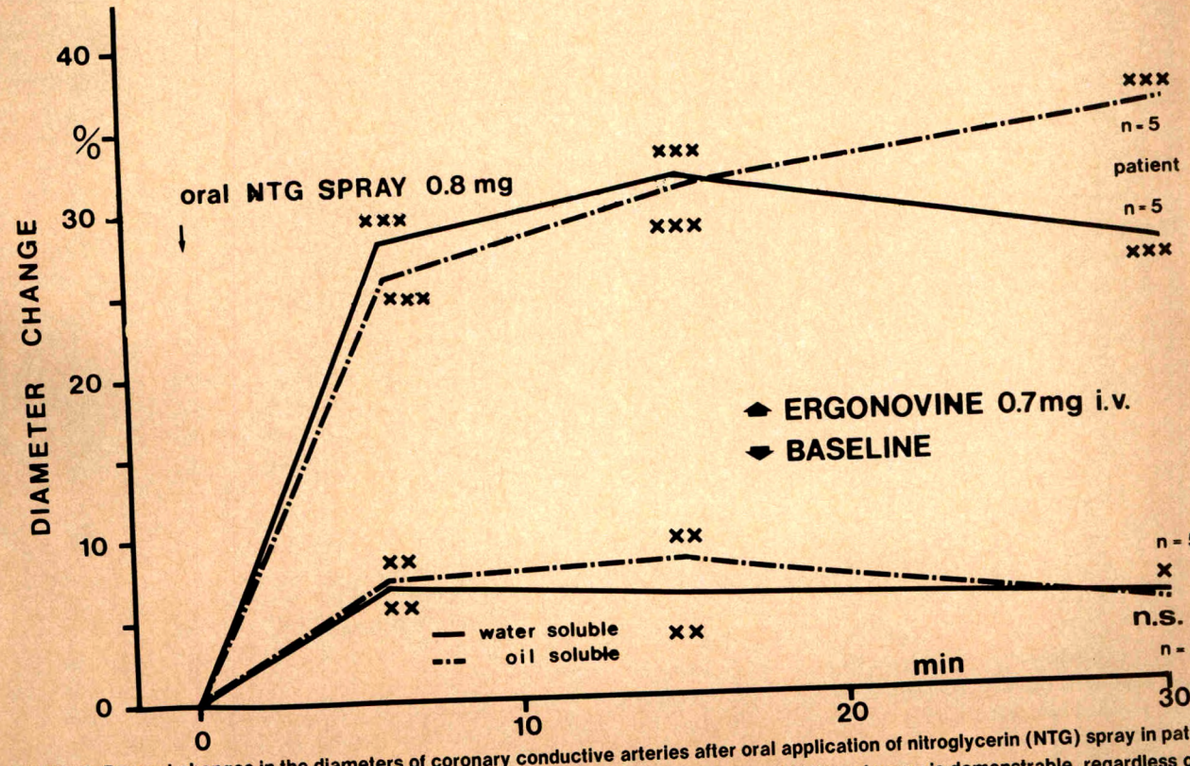

FIGURE 3. Percent changes in the diameters of coronary conductive arteries after oral application of nitroglycerin (NTG) spray in patients under resting conditions and during ergonovine provocation. Coronary dilative action of NTG oral spray is demonstrable, regardless of the galenic formulation, during a period of at least 30 minutes in group B patients undergoing ergonovine provocation. i.v. = intravenous; n.s. = not significant.

B. Coronary diameters at 6-, 15- and 30-minute intervals after administration of NTG oral spray were compared to diameters at rest in group A and to diameters at rest and after ergonovine provocation in group B. Changes in coronary diameters were calculated in millimeters and percent change.

Statistical methods: The significance of changes in coronary diameters within an individual patient was assessed by a Wilcoxon matched-pairs test. Significance of differences between NTG-h and NTG-l was determined by a Mann-Whitney U Test with regard to the extent and duration of action. Values at $p < 0.05$ were considered significant.

Results

Effect of nitroglycerin spray on coronary diameters at baseline: NTG oral spray induced a significant coronary vasodilation in group A patients: NTG-h increased coronary diameters from 2.40 ± 0.48 to 2.56 ± 0.51 mm ($p < 0.01$), 2.54 ± 0.55 mm ($p < 0.01$) and 2.53 ± 0.54 mm ($p < 0.01$) after 6, 15 and 30 minutes (Fig. 1). NTG-l increased coronary diameters from 2.64 ± 0.50 to 28.1 ± 0.44 mm ($p < 0.01$), 2.83 ± 0.43 mm ($p < 0.01$) and 2.74 ± 0.46 mm, respectively (difference not significant) (Fig. 1). There was a percent change in coronary diameters of 6.9, 6.0 and 5.2% after administration of NTG-h and a change of 7.4, 8.2 and 4.7% after administration of NTG-l (Fig. 3).

There was no significant difference between NTG-h and NTG-l in the extent and duration of vasodilative action in this group of patients.

Effect of ergonovine on coronary diameters at baseline: Intravenous ergonovine at a total dose of 0.7 mg decreased coronary diameters from 2.76 ± 0.72 to 2.45 ± 0.71 mm ($p < 0.001$) in group B patients who subsequently received NTG-h, and from 2.71 ± 0.62 to 2.37 ± 0.65 mm ($p < 0.01$) in group B patients who received NTG-l (Fig. 2). Compared with baseline values, this was a reduction in coronary diameters of 11.5 and 13.5%, respectively.

Effect of nitroglycerin spray on coronary vasoconstriction after ergonovine: NTG oral spray was efficacious in releasing ergonovine-induced coronary vasoconstriction in the group B patients: NTG-h spray increased coronary diameters after ergonovine from 2.45 ± 0.71 to 3.05 ± 0.60 mm ($p < 0.001$), 3.12 ± 0.62 mm ($p < 0.001$) and 3.00 ± 0.61 mm ($p < 0.001$), 3.12 ± 0.62 mm ($p < 0.001$) and 3.00 ± 0.61 mm ($p < 0.001$) at 6-, 15- and 30-minute intervals (Fig. 2 and 4). This was a 28.1, 31.5 and 27.0% diameter increase compared with diameters after ergonovine (Fig. 3), which exceeded baseline values by 12.4% ($p < 0.01$), 15.1% ($p < 0.01$) and 10.7% ($p < 0.05$), respectively. Coronary diameters after NTG-l measured 2.91 ± 0.63 mm ($p < 0.001$), 2.98 ± 0.53 mm ($p < 0.001$) and 3.10 ± 0.65 mm ($p < 0.01$), compared with 2.37 ± 0.65 mm after ergonovine (Fig. 2). There was a diameter increase of 25.6, 30.7 and 35.5% in relation to diameter narrowing after ergonovine (Fig. 2), and a diameter increase of 7.8% ($p < 0.05$), 11.6% ($p < 0.05$) and 15.5% ($p < 0.01$) compared with baseline values, respectively.

Whereas all changes of coronary diameters during ergonovine provocation and subsequent NTG application were statistically highly significant, no differences were seen when NTG-h and NTG-l oral spray in extent and duration of action were compared.

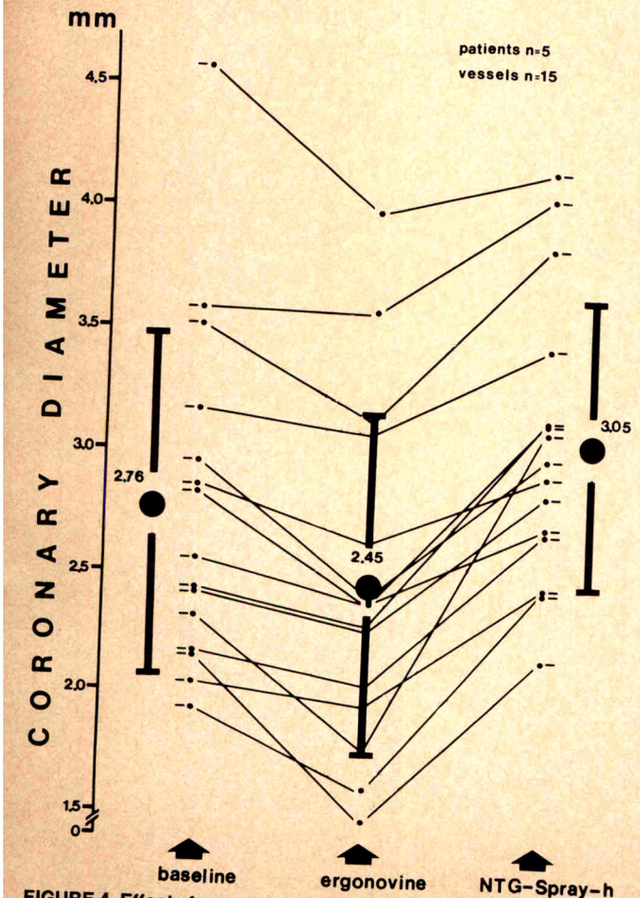

FIGURE 4. Effect of ergonovine and subsequent NTG-h oral spray on 15 coronary segments in the 5 group B patients who were randomized to NTG-h. Vasoconstriction after ergonovine and vasodilation after NTG was found to occur in a regular way in all of the coronary segments. NTG spray induces a marked coronary artery dilatation that exceeds dimensions at baseline. h = hydrosoluble.

Discussion

This study demonstrates for the first time the coronary artery dilating properties of NTG oral spray in patients with ergonovine-induced coronary vasoconstriction and the effectiveness of a new, hydrosoluble formulation of NTG oral spray. This new NTG spray, given orally at a dose of 0.8 mg, resulted in equal coronary vasodilative action compared with NTG oral spray in oily solution, which served as a standard in this study. Quantitative angiography demonstrated coronary vasodilation after NTG oral spray not only in patients under resting conditions but also in patients undergoing ergonovine-provocation. When NTG oral spray was given in addition to ergonovine, it counteracted not only the pharmacologically induced coronary vasoconstriction, but also increased coronary arteries above baseline diameters.

Hemodynamic investigations had priority to quantitative coronary angiography in this study, and there-

fore the onset of vasodilative action could not be assessed because of the 6-minute delay of the first angiographic control after NTG administration. But nevertheless, a marked coronary dilative action was demonstrable 6 minutes after administration of NTG spray and the duration of action was seen during a period of 30 minutes.

Further studies are needed to evaluate the onset of coronary dilative action of NTG spray by control angiograms within the first minute after its application.

The antianginal effect of NTG is mainly related to the reduction of preload and afterload with a concomitant decrease in both diastolic and systolic ventricular wall tension.[2] In addition to its reduction in myocardial oxygen demand, NTG has a coronary vasodilative action that improves myocardial oxygen supply, and this may contribute substantially to both the improvement of myocardial perfusion and myocardial performance.

NTG oral spray provides a method of achieving the beneficial effects of NTG in a more convenient way for the patient. It is evident from our hemodynamic studies that the new, hydrosoluble formulation of NTG oral spray has a more rapid onset of action compared with the conventional liposoluble NTG spray.

Sustained-Release Isosorbide Mononitrate (50 mg): Optimization of a Once-Daily Dosage Form for Long-Term Treatment of Angina Pectoris

RAINER BONN, PhD

A capsule formulation containing 50 mg of isosorbide mononitrate has been developed, 30% of which is in a nonsustained-release form to ensure rapid attainment of initial nitrate plasma levels. The remaining 70% is in a sustained-release form that ensures a long-lasting effect and the convenience of once-daily dosing. This formulation of sustained-release isosorbide mononitrate (Elantan® LA 50 mg) provides plasma levels greater than 100 ng/ml for 17 hours after oral administration. For the remaining 7 hours, the nitrate plasma level ranges between 50 and 100 ng/ml. (Am J Cardiol 1988;61:12E–14E)

The introduction of isosorbide 5-nitrate (isosorbide mononitrate [ISMN]) in the therapy of angina pectoris has facilitated long-term treatment. ISMN has a half-life of 4 to 5 hours and therefore has longer lasting effects than other nitrates. Nevertheless, this drug must be administered 2 to 3 times daily in the form of tablets, which releases the drug rapidly. From the viewpoint of a dosage schedule convenient to the patient, patient compliance and therapeutic reliability, there was a need to develop an ISMN preparation whose drug release is controlled (a sustained-release formulation) and allows once-daily administration.

Methods

The study was carried out in the form of a randomized crossover trial involving 18 male healthy volunteers, aged between 18 and 41 years (mean 25.5). Each subject received either 20 mg of ISMN (Elantan® tablets) twice daily or 50 mg of slow-release ISMN (Elantan LA 50) once daily over 5 days in a randomized crossover design. The tests were performed under conditions meeting GLP requirements by Simbec Research.[1] On the fifth day of the experiment, plasma concentrations were determined over the entire dosage interval, by high-performance liquid chromatography, using the procedure of Maddock et al.[2] No subject was subsequently excluded from the study.

Results

Plasma levels: Figure 1 shows the mean ISMN plasma concentration time curve after 50 mg of sustained-release ISMN (Elantan LA) had been taken once daily for 4 days. In the steady state, immediately before administration in the morning, the minimal plasma concentration of ISMN, c^{ss}_{min} was 40 to 50 ng/ml. After the conventional tablet (20 mg of ISMN twice daily every 12 hours), the corresponding value was 80 to 90 ng/ml. After administration of Elantan LA, the plasma concentration increased rapidly and reached a value of 300 ng/ml after 1 hour. The increase in concentration was then reduced, and after 6 hours a mean maximal concentration (c^{ss}_{max}) of 490 ng/ ml was reached. The concentration then slowly declined. Plasma ISMN levels of over 100 ng/ml were maintained for 17 hours, compared with 10 hours after conventional tablets.

The pharmacokinetic parameters relating to ISMN after the 2 preparations, obtained by averaging the individual values, are shown in Table I.

Retardation: According to Meier et al,[3] retardation of the release of an active drug compared with the normal dosage form can be characterized by the 2 retard quotients R_Δ (ratio of half-value duration) and R_c (ratio of c_{max} values). In this study, the half-value duration was prolonged by a factor of 2.4 ± 0.8, without significant elevation of the maximal plasma concentrations ($R_c = 1.2 \pm 0.4$).

Mean residence time of ISMN within the body was prolonged from 7.2 hours (Elantan tablets) to 9.8 hours (Elantan LA 50). The mean in vivo dissolution time of

the sustained-release preparation was therefore 2.6 hours. Relative bioavailability of Elantan LA 50 was 84% of Elantan tablets (differences were not statistically significant).

No adverse reactions were reported.

Discussion

Previous studies: Jansen et al[4] found a blunting effect (i.e., tolerance development) with regard to pulmonary artery pressure and working capacity when ISMN, 50 mg, was given 3 times daily at 8-hour intervals over a period of 4 weeks. When ISMN was reduced to 20 mg administered 3 times daily, no development of tolerance was observed.[5]

A pharmacokinetic analysis of ISMN plasma concentrations based on measured and calculated values according to the dosage regimen from Jansen allows the following interpretation (Fig. 2): After 50 mg of ISMN was administered 3 times daily at 8-hour intervals, steady-state maximal plasma concentrations of more than 1,000 ng/ml and minimal plasma concentrations of approximately 500 ng/ml were obtained. After 20 mg of ISMN was administered 3 times daily, maximal plasma concentrations of less than 500 ng/ml and minimal levels of 150 ng/ml were achieved. After 20 mg of ISMN was given twice daily, the minimal levels decreased below 100 ng/ml.

It was concluded from these investigations that levels of ISMN above 500 ng/ml should be avoided, as should fluctuations between 500 and 1,000 ng/ml. Plasma concentrations of ISMN should range between 100 and 500 ng/ml during active phases of the day, but may decrease below 100 ng/ml during the "trough" or inactive phase.

Cowan[6] also suggests that "prophylaxis should be tailored to the individual to provide protection at times of maximum susceptibility to ischemia, while allowing nitrate levels to fall at other times," i.e., during the night.

Working hypothesis for the present study: One way of increasing the duration of action of ISMN, and thereby reducing the dosage frequency and improving

TABLE I Parameters Relating to the Assessment of Bioavailability and Retardation of Release from Sustained-Release Isosorbide Mononitrate (ISMN) (Elantan® LA)

Parameter	ISMN (20 mg Twice Daily)	ISMN Sustained-Release (50 mg Once Daily)
c^{ss}_{min} (0)(ng/ml)	87 ± 47	38 ± 21
c^{ss}_{min} (τ)(ng/ml)	76 ± 47	44 ± 40
c^{ss}_{max}(ng/ml)	436 ± 138	488 ± 129
AUC^{ss}(ng h/ml)	2,377 ± 751	5,029 ± 1,272
MRT(h)	7.2 ± 0.8	9.8 ± 0.9

Values are expressed as mean ± standard deviation.

AUC = area under the curve; R_c = 1.21 ± 0.44; R_Δ = 2.35 ± 0.83; Relative bioavailability = 83.9 ± 6.7; c^{ss}_{min} = steady-state minimal plasma concentration; c^{ss}_{max} = steady-state maximal plasma concentration.

Retard quotients: R_c = ratio of c_{max} values; R_Δ = ratio of half-value duration; MRT = mean residence time.

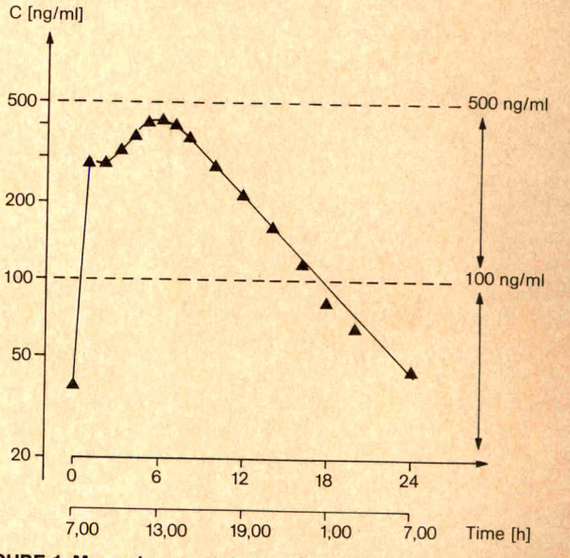

FIGURE 1. Mean plasma concentration of isosorbide mononitrate in 18 healthy volunteers after administration of 50 mg of sustained-release Elantan® LA 50 for 4 days. Semilogarithmic scale.

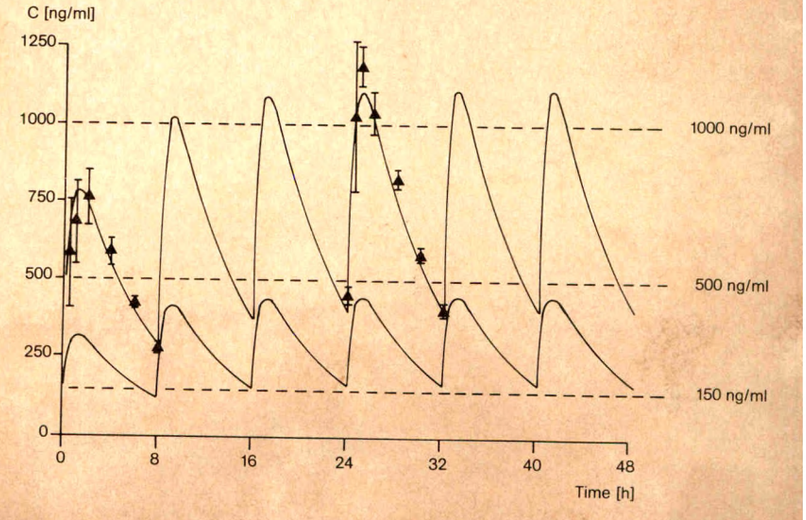

FIGURE 2. Measured (▲) and calculated (—) plasma concentrations of isosorbide mononitrate after oral administration of 20 mg 3 times daily (*lower curve*) and 50 mg 3 times daily (*upper curve*). The dosage interval was 8 hours in all cases. Steady-state concentrations were reached after the fourth dose.

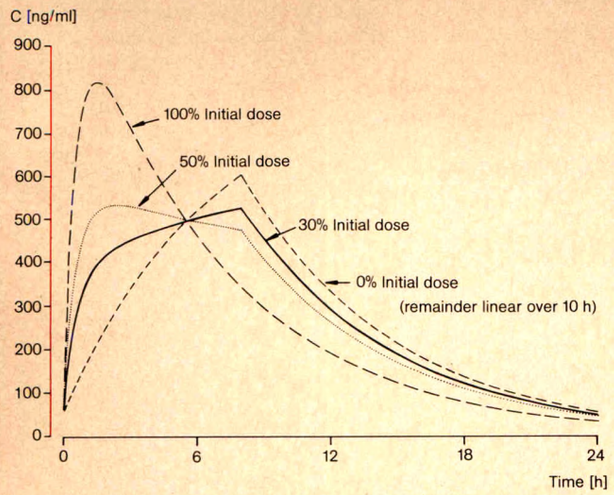

FIGURE 3. Calculated isosorbide mononitrate plasma concentration curves after oral administration of 50 mg in sustained-release form and in nonsustained-release form.

patient compliance, is to coat the active drug with a sustained-release capsule. To achieve optimal plasma levels, the design of the sustained-release matrix is extremely important.

If all of the nitrate is released continuously in vivo over a period of 8 hours (i.e., if there is no initial release dose), a slow increase in plasma nitrate concentrations would be expected, with a maximal concentration after 8 hours. The minimal therapeutic level of 100 ng/ml would be reached relatively late, leaving the patient unprotected.

This "lag-period" can be reduced by an initial nonsustained-release dose. If this is 35% of the total nitrate content and the sustained-release dose would be absorbed linearly over 8 hours, persistently high or plateau plasma concentrations would be expected over a lengthy period (Fig. 3).

If this initial dose is greater than 35%, the maximal concentration would be reached shortly after administration, decreasing slowly. If the initial dose is less than 35%, the maximal plasma nitrate concentration would be reached after 8 hours. Therefore, an initial dose of 30% of the total was used (Fig. 3), which led to an increase in nitrate plasma levels for 6 hours, followed by a slow decline. This ratio is in accordance with the current opinion regarding the prevention of nitrate tolerance.[5–10]

Conclusions

This preparation of sustained-release ISMN, 50 mg (Elantan LA 50), reached a plasma concentration of 300 ng/ml after 1 hour. The nitrate plasma level remained above 100 ng/ml for 17 hours after administration. During the remaining 7 hours, plasma nitrate levels ranged between 50 and 100 ng/ml, which may offer protection against silent (i.e., asymptomatic) myocardial ischemia and slight physical stress. Clinical studies with this 50-mg formulation have demonstrated significant antianginal efficacy when compared with placebo therapy after acute[11] and subacute[12] dosages, and no tolerance development after 3 and even 12 months of therapy.[13–15] This 50-mg nitrate formulation is suitable for once-daily dosage.

Nitrates and Calcium Antagonists for Silent Myocardial Ischemia

THOMAS VON ARNIM, MD, and ANDREA ERATH, MD

Continuous Holter monitoring of patients with coronary heart disease can show transient ischemic episodes occurring spontaneously with or without angina throughout the day. A controlled double-blind trial was conducted comparing the effects of isosorbide-5-mononitrate (IS-5-MN) and nifedipine in patients with documented transient ischemic episodes. Seventy-five percent of the ischemic episodes were not accompanied by pain. Twenty patients with documented coronary heart disease were included; 15 finished the 4-week study (1 patient had headaches, 1 thyrotoxicosis, 1 hypertensive crisis and 2 unstable angina). On a dual-channel FM-recorded electrocardiogram, ischemic episodes were counted when ST deviation was >1 mm for >1 minute. Patients received IS-5-MN (20 mg 3 times a day or 50 mg in a sustained-release tablet) or nifedipine (20 mg in a sustained-release tablet 3 times a day) in random order over four 1-week periods. At the end of each week, Holter monitoring was repeated and showed reductions of episodes by 67% and 67% after weeks of IS-5-MN therapy and 56% and 58% after weeks of nifedipine therapy (all p <0.05). Painful and painless episodes were reduced to a similar extent. Individual responses showed great variability, and in all treatment periods not more than half of the patients were completely free of ischemic episodes. One of the 12 patients did not respond to either way of treatment. It is concluded that (1) treatment effects for transient, predominantly silent, ischemia can be documented with continuous Holter monitoring; (2) both IS-5-MN and nifedipine reduce ischemic episodes by about 60%; and (3) large variability and incomplete response in some patients may make combination treatment a reasonable choice.

(Am J Cardiol 1988;61:15E–18E)

Several investigators[1–4] have shown that transient ischemia with or without angina pectoris can be objectively documented by ambulatory electrocardiographic (ECG) monitoring. With use of careful nuclear medical studies,[5] transient ST changes have been validated to represent true ischemia in patients with severe underlying coronary disease.

If ambulatory monitoring can objectively document ischemia in patients throughout the day, then it would appear reasonable to use this technique for the objective assessment of treatment effects. We therefore conducted a double-blind trial, comparing the influence of 2 well-known antianginal drugs, isosorbide-5-mononitrate (IS-5-MN) and nifedipine, on episodes of transient ischemia in patients with documented coronary heart disease.

Method

Patients: The study included consecutive outpatients of our department, who had coronary heart disease documented either by coronary angiography or by definite myocardial infarction from history and ECG criteria, and who had more than 1 transient ischemic episode on ambulatory monitoring when they were not taking long-acting nitrates or calcium antagonists.

We included 20 such patients (14 men and 6 women, median age 64 years). All patients gave informed consent. During the study 5 patients had to be withdrawn for the following reasons: severe headaches (n = 1), development of thyrotoxicosis (n = 1), hypertensive crisis (n = 1) and unstable angina (n = 2). The following results are based on evaluation of the remaining 15 patients.

Ambulatory electrocardiographic monitoring: The method of ambulatory monitoring with analysis of ST-segment changes has been described elsewhere.[6] A typical example of an ischemic episode with ST-segment depression is seen in Figure 1. Frequency-modulated dual-channel recordings were used over 24

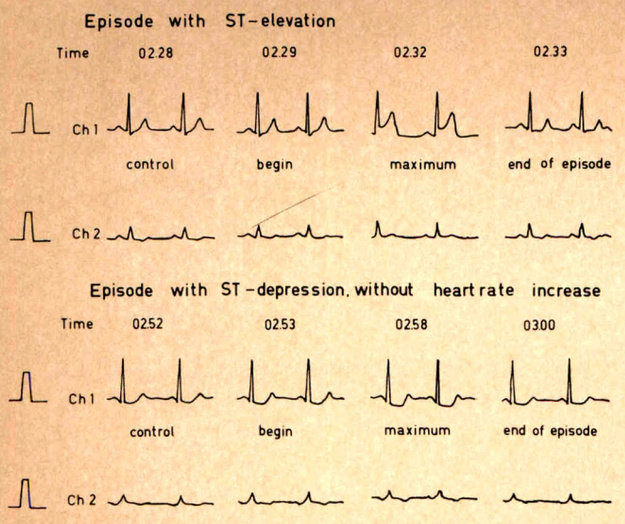

FIGURE 1. Examples of transient ischemic episodes as recorded with frequency-modulated ambulatory electrocardiographic monitoring. With visual analysis, episodes are detected and an example of the electrocardiogram before, at the beginning, at maximal ST deviation and at the end of the episode is documented. Episodes are counted when the ST deviation is >1 mm (0.1 mV) for more than 1 minute.

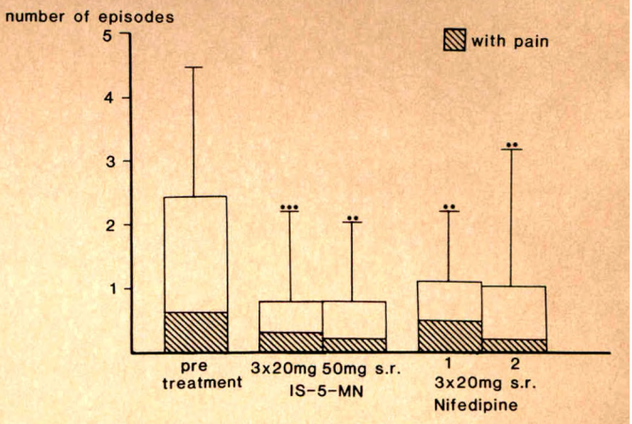

FIGURE 2. Comparison of the frequency of transient ischemic episodes in 15 patients with coronary heart disease before treatment and during 4 randomized weeks of treatment with isosorbide-5-mononitrate or nifedipine. For the patients as a group there is a significant reduction in the frequency of ischemic episodes, which is similar for painful and painless ischemia. s.r. = sustained release.

hours on an Oxford Medilog 2 system with visual analysis. Episodes were identified and examples of the beginning of the episode, 1 minute before the episode, maximal ST changes and the end of the episode were documented. Ischemic ST-segment deviations of >1 minute and >1 mm from the baseline ECG complex were counted as episodes (calibration 10 mm for 1 mV).

Study protocol: Patients were treated in a double-blind crossover randomized fashion for 4 periods of 1 week each. There were 2 periods during which patients received 20 mg nifedipine 3 times daily in sustained-release form. One treatment period consisted of 20 mg of IS-5-MN administered 3 times daily and 1 period consisted of the drug in sustained-release form, 50 mg once daily. Repeated ambulatory ST-segment monitoring for 24 hours was performed at the end of each weekly treatment period. Patients had an event button to mark anginal pain on the ECG recorders and they were asked at the end of each recording period for the number of occurrences of anginal pain and the possible adverse effects of the treatment.

Statistical evaluation: Results between different treatment periods and the period without treatment were compared by the Wilcoxon rank-sum test. Results were considered significant at $p < 0.05$.

Results

During all treatment periods the number of transient ischemic episodes decreased significantly. There were no significant differences between mononitrate and calcium antagonist treatment. The proportion of symptomatic ischemic episodes was 25% during the treatment period and did not change significantly. Therefore, effects of both drugs on symptomatic and asymptomatic episodes of myocardial ischemia were similar (Fig. 2). The large standard deviations seen in Figure 2 show a considerable variability of response.

The total duration of ischemic episodes was also significantly reduced during all treatment periods, from 52 minutes in the pretreatment period to 16 and 17 minutes during treatment with IS-5-MN and 18 and 25 minutes in the nifedipine treatment period. We developed an ischemia score compiling the millimeters of ST depression multiplied by the minutes for each episode. With this ischemia score, the severity of the "total ischemic burden" can be compared between different periods of observation. The score was also significantly reduced during 3 treatment periods in our patients. During 1 of the 2 nifedipine periods the reduction was not significant ($p = 0.075$). However, there was great variability in the responses (Table I). In Table I, the ischemia score is given for each patient and each treatment period. Different types of responses occurred. Some patients had a complete response with both treatments (patients 7, 14, 15 and 18). Some patients responded only to mononitrate (patients 9 and 20). Some patients responded only to nifedipine (patient 16). Others were partial responders, and 1 patient (patient 4) must be considered a nonresponder to both ways of treatment. Thus, the overall response of our group of patients, shows a wide variety of responses, which can be basically different between individual patients.

Discussion

To test the anti-ischemic efficacy of drug treatment, exercise testing has been used most often. Exercise testing with ECG or radionuclide markers of ischemia has the advantage of a clear-cut test situation, in which at least the mode of testing can be standardized and

easily reproduced. This leads to a reasonable reproducibility of exercise test results.[7] In recent years, however, cardiologists have become increasingly aware of the dynamic nature of coronary stenoses that produce ischemia and of the importance of ischemia occurring with or without angina in some patients at very variable degrees of physical activity.

It seems logical therefore to test drugs, which are known for their antianginal effects, with a method that is able to detect myocardial ischemia independently of exercise throughout a 24-hour day. Ambulatory ECG monitoring can be used for this purpose. However, this approach has the definite drawback of a high degree of variability in the occurrence of transient spontaneous ischemic episodes.[8,9] On the other hand, ambulatory monitoring is the only method to date that is widely applicable and can follow the patient for any signs of ischemia when he is out of the hospital and not in an exercise testing environment.

This study tried to overcome the problems of variability by a randomized crossover design that enabled us to compare 2 periods of treatment with mononitrate and 2 periods of treatment with the calcium antagonist nifedipine with a pretreatment period. There was a significant beneficial effect of treatment from both drugs in patients who completed the study. This finding applies to the patients as a group and comprises markedly different responses in individual patients. A large number of patients (5 of 20) could not complete the 4-week study period according to the protocol. Only 1 patient had to discontinue medications because of an adverse effect (nitrate headache). However, 2 patients, considered to have stable angina at entry into the study, had unstable angina with an increasing number of attacks of severe rest angina. This finding suggests that patients who appear to have stable angina but do have frequent ischemic episodes on ambulatory monitoring may not really be in a stable phase of their disease.

In our trial, 2 methods of medical treatment of angina were compared: IS-5-MN and isosorbide dinitrate. IS-5-MN has a markedly improved bioavailability when compared with isosorbide dinitrate. It is still a matter of discussion whether the sustained-release formulation of IS-5-MN is preferable from a pharmacodynamic point of view.[10] For patient compliance, however, once-daily dosage is of great advantage.

Studies from our group and others[4,11,12] have shown that there are no ECG features, heart rate differences or differences in duration of episode, that would allow a clear distinction between symptomatic and silent ischemic episodes. Thus, one would assume that drugs known to be effective for symptomatic episodes should be just as effective for episodes of silent ischemia. In this study, painful and painless ischemic episodes were reduced in parallel fashion. Other investigators have also reported effective reduction of symptomatic and asymptomatic ischemic episodes.[13,14] In this study, IS-5-MN was as effective as nifedipine in reducing ischemic episodes. These results are in keeping with other studies comparing isosorbide dinitrate and nifedipine therapy.[15-18] However, a considerable number of our patients are not treated satisfactorily with either drug alone, and therefore a combination of treatments may be preferable.

Comparative Evaluation of Isosorbide-5-Mononitrate and Nitroglycerin in Chronic Congestive Heart Failure

ADAM SCHNEEWEISS, MD

The hemodynamic effects of isosorbide-5-mononitrate (IS-5-MN) and nitroglycerin were compared in 10 patients with chronic congestive heart failure (CHF). Both drugs were given intravenously, at an infusion rate individually titrated to achieve a maximal increase in cardiac output and a maximal decrease in pulmonary capillary wedge pressure. Both drugs produced the typical hemodynamic responses to nitrates, the most prominent of which were decreases in pulmonary capillary wedge, pulmonary arterial and right atrial pressures, and an increase in cardiac output. Several differences in the response to these 2 drugs were observed. Pulmonary capillary wedge pressure was reduced from 31.5 ± 3.0 to 19.6 ± 5.0 mm Hg with nitroglycerin and to 15.0 ± 3.12 mm Hg with IS-5-MN. Both the absolute and the percent decrease with IS-5-MN were significantly greater ($p < 0.05$) than those observed with nitroglycerin. Mean systemic arterial pressure was reduced from 89.2 ± 11.3 to 79.8 ± 10.8 with IS-5-MN (difference not significant) and to 67.5 ± 7.7 mm Hg with nitroglycerin ($p < 0.01$). The difference, both in absolute and percent reductions, was statistically significant. Thus, in patients with chronic CHF, IS-5-MN produced a greater decrease in pulmonary capillary wedge pressure (the major beneficial effect of nitrates in this condition) and a smaller decrease in systemic arterial pressure (the potentially deleterious effects of nitrates). These findings indicate a potential advantage of IS-5-MN over nitroglycerin in patients with CHF, particularly in those with CHF of ischemic etiology.

(Am J Cardiol 1988;61:19E–21E)

Isosorbide-5-mononitrate (IS-5-MN) is a metabolite of isosorbide dinitrate that possesses pharmacologic activity qualitatively similar to that of the parent drug, and a more predictable pharmacokinetic profile.[1–5] It was found effective in all indications for which nitrates are used including congestive heart failure (CHF).

One of the problems associated with nitrate therapy in patients with CHF is that the beneficial reduction in left ventricular filling pressure may be associated with an excessive decrease in systemic vascular resistance. This could be particularly deleterious in patients with coronary artery disease. Preliminary studies revealed that IS-5-MN may have a hemodynamic profile somewhat different from that of nitroglycerin. It may have a greater selectivity to capacitance vessels than to resistance vessels, compared with nitroglycerin. This study compares the hemodynamic responses to IS-5-MN and nitroglycerin in patients with chronic CHF.

Methods

Patients: Ten patients (7 men and 3 women, mean age 68 ± 12 years) with chronic CHF were studied. The cause of heart failure was old myocardial infarction in 8 patients and dilated cardiomyopathy in 2. All patients signed an informed consent before the study.

Protocol: The patients were hospitalized in an intensive coronary care unit. All cardioactive drugs were gradually discontinued. A Swan-Ganz catheter was inserted and hemodynamic measurements were ob- tained at rest 2 hours after insertion. Heart rate, temic, pulmonary arterial, right atrial and pul- capillary wedge pressures and cardiac were measured and systemic and pulmonary sis- tance were calculated. IS-5-MN was travenously in 5 patients, and nitr maining 5. The initial infusion and it was individually titrate increase in cardiac output an mean pulmonary capillary w

modynamic measurements were obtained at the time of maximal response (which was achieved in all patients within 24 hours), the drugs were gradually discontinued and the patients were allowed to stabilize at the pretreatment hemodynamic condition. They were then crossed over to the other drug and the same procedure was repeated.

The absolute changes in hemodynamic parameters, the percent changes in these parameters and the levels achieved at maximal therapy were compared. Paired *t* test was used to determine statistical significance.

Results

The doses that achieved maximal effect were 6.5 mg/hour for IS-5-MN and 6.0 mg/hour for nitroglycerin. Control hemodynamic parameters were similar in the pretreatment and stabilization periods, after discontinuation of the drugs in the first phase and before crossover to the other drug.

IS-5-MN significantly reduced diastolic systemic arterial, right atrial, systolic, diastolic, mean pulmonary arterial and pulmonary capillary wedge pressures and pulmonary vascular resistance, and increased cardiac output. Nitroglycerin produced qualitatively comparable effects, except for the decrease in pulmonary vascular resistance, which was nonsignificant. In addition, nitroglycerin, but not IS-5-MN, decreased systemic systolic blood pressure (Tables I and II). This effect on systolic blood pressure was 1 of the 2 major differences between both drugs. Mean systemic

* Difference between the effects of both drugs.
Abbreviations as in Table I.

blood pressure was reduced by 9.8% with IS-5-MN and by 22.8% with nitroglycerin. The difference was statistically significant ($p < 0.01$). Moreover, the percent reduction in systemic vascular resistance was significantly greater with nitroglycerin than with IS-5-MN.

In the presence of this greater decrease in arterial pressure with nitroglycerin, this drug reduced the mean pulmonary arterial pressure less than IS-5-MN (28.3 ± 19.1% and 41.0 ± 15.1%, respectively; $p < 0.01$).

Discussion

Our findings indicate that the hemodynamic response to IS-5-MN in patients with chronic CHF resembles, in general, the response to other nitrates.[6-9] The main effect is a decrease in left ventricular filling pressure, which is associated with some increase in cardiac output. However, when compared with nitroglycerin, important quantitative differences in the hemodynamic profile have been observed. The decrease in left ventricular filling pressure was greater and the filling pressure achieved was lower with IS-5-MN than with nitroglycerin. This was found in the presence of a greater reduction in systolic and mean blood pressures, and achievement of lower systolic and mean blood pressures with nitroglycerin compared with IS-5-MN (all differences statistically significant). The cause of this difference is not known.

This hemodynamic profile of IS-5-MN determines its clinical use, provides a safety factor in treatment of certain patients and allows some selectivity of nitrate therapy in various conditions. Obviously IS-5-MN is most suitable for treatment of patients with CHF who mainly have symptoms of pulmonary congestion. This drug may be safer than nitroglycerin in patients with heart failure of ischemic etiology, because it is less likely to lower the coronary perfusion pressure excessively. It is important to confirm this hypothesis in patients with acute-onset heart failure complicating acute myocardial infarction.

Rabinowitz et al[10] studied the hemodynamic effects of intravenous IS-5-MN in 17 patients with CHF complicating an acute (10 patients) or old (7 patients) myocardial infarction. The infusion rate was titrated to achieve maximal effects. The maximal doses used reduced mean pulmonary capillary wedge pressure from 25.4 ± 4.6 to 18.3 ± 5.9 mm Hg, right atrial pressure from 9.1 ± 5.6 to 6.3 ± 4.2 mm Hg, and systemic vascular resistance from 1,778 ± 426 to 1,610 ± 298 dynes s cm^{-5}.

The effect of IS-5-MN in the patient with acute or chronic CHF was comparable to that found in our patients. Thus, the differences between IS-5-MN and nitroglycerin found in our study may also be observed in acute-onset CHF.

Moreover, Rabinowitz et al[10] found a greater response of systemic vascular resistance in patients with chronic heart failure than in those with acute heart failure. This suggests that the advantages of IS-5-MN may be more prominent in acute CHF.

Emergency Treatment of Severe Cardiogenic Pulmonary Edema with Intravenous Isosorbide-5-Mononitrate

CHARLES HARF, MD, and ROBERT WELTER, MD

Intravenous isosorbide-5-mononitrate (IS-5-MN) was administered to 24 patients, mean age 73, with severe respiratory distress after pulmonary edema and acute left heart failure. The condition was due to ischemic cardiopathy in 18 patients (4 with acute myocardial infarctions), congestive cardiomyopathy in 3, hypertensive cardiopathy in 2, and mitral valvular disease in 1. Therapy consisted of an intravenous (i.v.) bolus dose of IS-5-MN, followed by a continuous infusion (mean 8 mg/hour over 24 hours) of i.v. furosemide and additional oxygen. Clinical data were recorded as well as blood gas values and repeated chest radiographs. All patients survived and improved markedly; only 6 needed mechanical ventilation. Most patients had fast respiratory relief, with no untoward reaction, except a brief decrease of blood pressure in a ventilated patient taking morphine. These data indicate that i.v. IS-5-MN is effective and safe for the management of severe acute cardiogenic pulmonary edema.

(Am J Cardiol 1988;61:22E–27E)

Acute pulmonary edema after left ventricular failure represents a life-threatening medical emergency dominated by respiratory distress and hypoxemia. The treatment is aimed at a prompt reduction of the increased capillary pulmonary wedge pressure, responsible for a transudation of fluid in the alveoli.[1]

Nitrates are potent venodilators and consistently lower left ventricular filling pressure by venous pooling. Although nitrates are predominantly preload-reducing agents, they are able to cause a decrease in systemic vascular resistance and an increase in cardiac output.[2–4] Parenteral administration seems preferable in the critically ill to achieve therapeutic levels in the shortest time, the continuous infusion permitting a precise, homogenous dosage. Intravenous (i.v.) isosorbide dinitrate (ISDN) has been shown to be a valuable and safe treatment in acute left pump failure.[5–8] Isosorbide-5-mononitrate (IS-5-MN) is the main metabolite of ISDN, sharing similar pharmacologic activity, with a clearer pharmacokinetic profile.[9] To assess the efficacy, tolerability and safety of i.v. IS-5-MN, we undertook an open, clinical study in 24 patients admitted to our intensive care unit with acute cardiogenic pulmonary edema.

Methods

Patients: We studied 24 consecutive patients (14 men and 10 women, aged 56 to 88 years [mean 72]) admitted to the intensive care unit for respiratory distress related to acute left heart failure with pulmonary edema (Table I). Acute left ventricular failure was clinically manifest. All patients had extreme dyspnea, cyanosis, gallop rhythm and extended lung crepitations (with frothy sputum in 17). Arterial blood gases showed marked hypoxemia, and there was radiologic evidence of extended interstitial and alveolar edema and cardiomegaly. Most patients had not responded to previous diuretic therapy. Patients were excluded from the study because of shock, systemic hypotension (systolic blood pressure <100 mm Hg), a major renal insufficiency, or when long-acting nitrates had been administered during the last 24 hours.

The cause of acute failure was acute myocardial infarction in 4 patients (3 anterior, 1 inferior localization) and chronic ischemic cardiopathy with recurrent myocardial infarctions in 14 (6 with hypertension). In the remaining 6 patients, 3 had congestive cardiomyopathy, 2 hypertensive cardiopathy and 1 mitral valve disease.

Procedure: Baseline measurements of respiratory rate, heart rate, and systolic and diastolic blood pressures were recorded, the mean arterial pressure being calculated as follows: MP = DP + 1/3 (SP − DP) mm Hg, where MP = mean arterial pressure, DP = diastolic pressure, and SP = systolic pressure. The grade of dyspnea and the extent of wet rales were assessed and noted from 0 to ++++.

Blood gases: Hydrogen ion concentration, $paCO_2$ and paO_2 were determined from arterial blood without additional oxygen (ABL 2 Radiometer). A bedside chest radiograph showed the grade of cardiomegaly and the extent of interstitial and alveolar edema. After starting therapy, clinical data were collected after 0.5, 1, 2, 4, 6, 9, 12, 18 and 24 hours. The hourly diuresis was measured by a vesical catheter. Blood gas values were controlled at 2, 4, 6, 12, 18 and 24 hours, while the thorax radiograph was repeated after 6, 12 and 24 hours.

IS-5-MN administration began with an i.v. bolus dose of 10 mg, repeated after 10 minutes if necessary and followed by a continuous infusion of 1 mg/ml concentration for 24 hours. The rate ranged from 4 to 15 mg/hour, depending on the weight and condition of the patients. Additional therapy, oxygen and i.v. furosemide, was administered to all patients. Digoxin, theophyllin and antiarrhythmic therapy was administered when necessary.

Statistical methods: Statistical evaluation of data was done by means of exploratory data analysis according to the design of the study as an open clinical trial without randomization. Values after infusion of i.v. IS-5-MN were compared with baseline values by means of the Wilcoxon-Pratt signed-rank test.

Results

Therapy: Therapy consisted of a bolus dose of IS-5-MN (mean 13.45 ± 8.14 mg). The infusion rate was 8.08 ± 3.71 mg/hour for 6 hours, 7.89 ± 2.85 mg/hour for 24 hours or 0.12 mg/kg/hour. The mean dose of furosemide was 53.91 ± 28.56 mg at 6 hours and 63.48 ± 27.4 mg at 12 hours. Most patients were given 40 mg i.v. at the beginning of the study (except in 6 cases, in which administration was delayed for 2 hours) (Table II). Six patients received theophyllin because of bronchospasm; another 6 received digoxin for tachyarrhythmia. Amiodarone and lidocaine were administered 5 times.

All patients survived and could be dismissed from the intensive care unit within 48 hours with oral IS-5-MN. Only 6 needed mechanical ventilation, 5 immediately after admission because of extreme asphyxia, coma or respiratory arrest, and the sixth, an 88-year-old woman, after 9 hours of therapy because of aspiration of vomitus. The duration of intubation ranged from 9 to 27 hours (mean 17.5). The 18 nonventilated patients had marked symptomatic improvement and, despite initial severe respiratory distress, avoided mechanical ventilation. Fourteen of them had a rapid relief of dysnpea (within 5 to 10 minutes after a bolus injection) with color returning to the extremities. In the remaining 4, respiratory amelioration occurred after

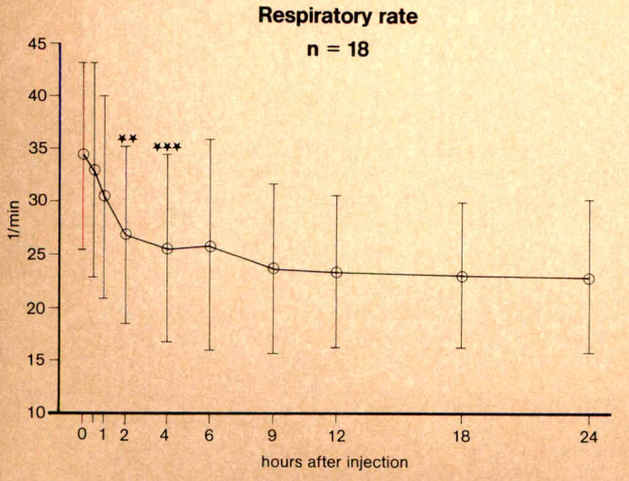

FIGURE 2. Respiratory rate over the 24-hour study period, excluding the ventilated patients. *Bars*, standard deviation. **p <0.01; ***p <0.001 compared with baseline values.

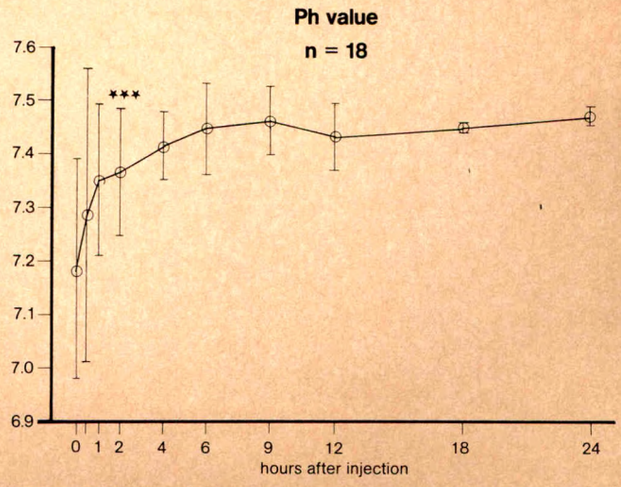

FIGURE 4. Hydrogen ion concentration (Ph) over the 24-hour study period, excluding ventilated patients. *** p <0.001 compared with baseline values.

90 minutes. A marked regression of the grade of dyspnea appeared within 2 hours, with similar decline of the lung crepitation (Fig. 1).

Mean respiratory rate decreased from 36 ± 7 cycles/min before treatment to 27 ± 8 cycles/min at 2 hours (−22.9%, $p < 0.001$), with further reduction at 9 hours (Fig. 2). Baseline blood gas values showed marked hypoxemia in all nonventilated patients: paO_2 53.9 ± 5.7 torr. A significant improvement to 61.8 ± 13.4 torr occurred at 2 hours ($p < 0.01$), with little further change. The increase from baseline to that at 24 hours was highly significant ($p < 0.001$) (Fig. 3). Acidosis (pH <7.30) was present in 13 patients. Mean values increased from a pH of 7.214 ± 0.12 to a pH of 7.39 ± 0.058 at 2 hours ($p < 0.001$) without bicarbonate administration (Fig. 4). Thirteen patients were hypercapnic at admission ($paCO_2 > 40$ torr). $PaCO_2$ decreased from 48 ± 10.4 to 34.4 ± 7.7 torr at 2 hours (−23.9%, $p < 0.001$) (Fig. 5). Heart rate decreased from 118 ± 19 to 105 ± 19 beats/min at 1 hour (−11%, $p < 0.001$), stabilizing under 100 beats/min at 2 hours (Fig. 6).

Systemic blood pressure: Systemic, diastolic and mean arterial pressures decreased significantly at 1 hour with mean pressure decreasing from 124 ± 28 to 112 ± 15 mm Hg (−9.7%, $p < 0.01$); difference with baseline values was maximal at 6 hours (−16.1%, $p < 0.001$) (Fig. 7). Mean arterial pressure decreased in patients with high initial values, but was not affected in the others (Fig. 8). A rapid onset of marked diuresis occurred in all patients in combination with i.v. furosemide (1,000 ml was reached at 4 hours) (Fig. 9). The degree of radiographic pulmonary edema improved in all patients throughout the subsequent 24 hours of therapy.

Adverse effects: Blood pressure decreased to 80/60 mm Hg, with a decrease in diuresis at 20 minutes in 1 patient ventilated at admission when 10 mg of i.v. morphine had been given because of agitation. After discontinuing IS-5-MN infusion, blood pressure increased to 100/65 mm Hg at 1 hour with new onset of diuresis. No other untoward incident was noted. The 4 patients with acute myocardial infarctions had fast relief of pain and their course was uncomplicated. There was no complaint of headache.

Discussion

Severe pulmonary edema in acute left ventricular failure represents a critical situation that demands prompt resolution. Hemodynamically, systemic arterial pressure is often elevated and cardiac output may be decreased to such an extent that systemic vascular resistance is increased. Left venricular end-diastolic and pulmonary capillary pressures are strikingly increased, leading to transudation of fluid in the alveoli with resultant respiratory distress,[10] The major objective of treatment is the rapid reduction of left ventricular filling pressure.

Nitrates offer substantial advantages over conventional diuretic drugs[11] and phlebotomy and thus appear to be the drug of choice.[5,12–14] They consistently reduce left ventricular filling pressure by potent venodilation and venous pooling. In patients with severe heart failure, they increase cardiac output by decreas-

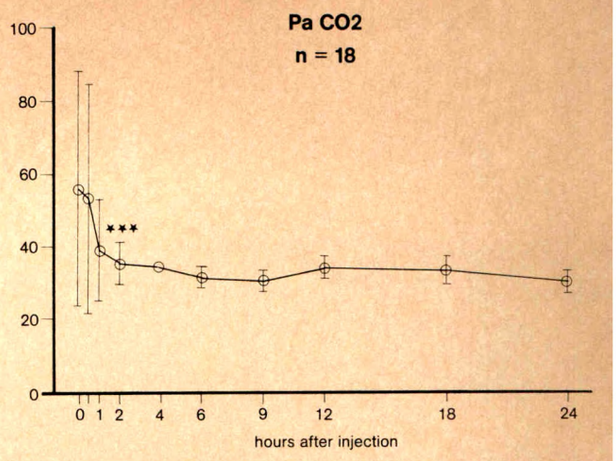

FIGURE 5. Partial arterial CO_2 pressure ($PaCO_2$) over the 24-hour study period (in torr), excluding ventilated patients. ***p <0.001 compared with baseline values.

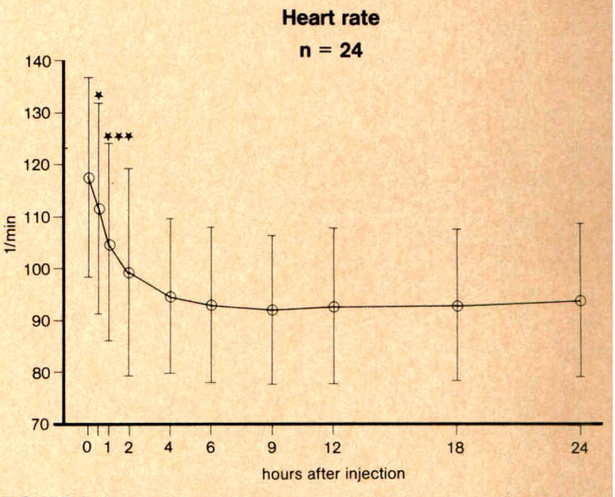

FIGURE 6. Heart rate over the 24-hour study period. *p <0.05; ***p <0.001 compared with baseline values.

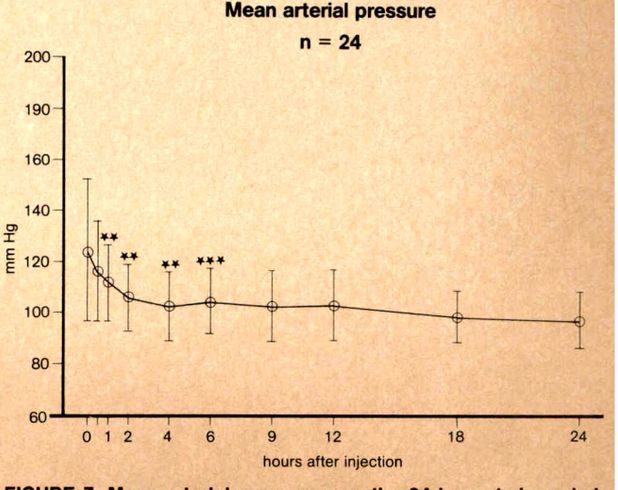

FIGURE 7. Mean arterial pressure over the 24-hour study period. **p <0.01; ***p <0.001 compared with baseline values.

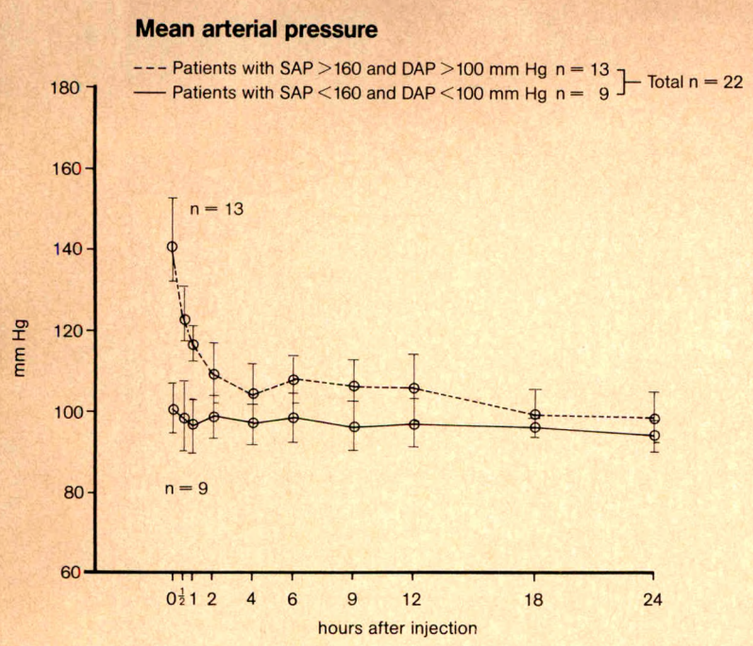

FIGURE 8. Mean arterial pressure over the 24-hour study period in hypertensive and normotensive patients. Hypertensive patients: systolic pressure (SAP) >160 mm Hg; diastolic pressure (DAP) >100 mm Hg; Normotensive patients: SAP <160 mm Hg; DAP <100 mm Hg.

ing systemic vascular resistance. In patients with ischemic heart disease, they improve parietal dyskinesia by parietal tension reduction and improve regional myocardial perfusion, and in those with mitral valvular insufficiency, nitrates decrease regurgitant blood volume.[1,2,4,15]

One of the major problems in nitrate therapy is the risk of severe arterial hypotension after an excessive decrease in systemic vascular resistance, with aggravation of ischemic heart disease.[2]

Parenteral administration is a logical course of therapy in the very ill patient, because of rapid onset of action and avoidance of the uncertainties of tolerance and absorption.

In patients with acute pump failure, nitroglycerin and i.v. ISDN have been widely used, with great benefit.[6–8,11] IS-5-MN, the main metabolite of ISDN, has qualitatively similar pharmacologic activity, but offers a longer elimination half-life, better predictability and good correlation between pharmacokinetics and effects.

In patients with severe acute pulmonary edema, therapeutic levels have to be achieved in the shortest time possible. For this reason, an initial i.v. bolus dose was used, followed by continuous infusion of concentrated IS-5-MN, permitting precise dosage and homogenous plasma levels, with a reduced fluid intake.[16] The aim of this open clinical trial was to assess the value and efficacy of this mode of administration of IS-5-MN and its safety of use in the daily practice. It is not often practical or possible to place a Swan-Ganz catheter in the pulmonary artery before starting therapy in patients with extreme dyspnea. Therefore, diagnosis of acute pump failure was established on clinical ground with the monitoring of blood gas, and electrocardiographic and radiologic changes; therapy was administered under clinical monitoring. Our elderly patients were all in very critical condition, representing a particularly severe selection of acute left ventricular failure, as seen on the baseline clinical, blood gas and radiologic findings. The results demonstrate the efficacy and tolerability of i.v. IS-5-MN.

All patients had marked symptomatic improvement with IS-5-MN; only 6 had to be ventilated. A prompt relief of dyspnea often followed the initial bolus. In the 4 nonventilated patients, in whom regression of dyspnea was slower, 2 major bronchospasms and 1 acute bronchitis were noted. A rapid improvement of arterial oxygenation is required in these presentations of pulmonary edema, when severe hypoxemia dominates. A significant increase of paO_2 was seen within 2 hours, permitting hemoglobin saturation of >90%. Metabolic and respiratory acidosis with hypercapnia normalized without additional therapy.

Elevated heart rate and systemic blood pressure decreased to normal values after 1 hour, with marked significance in mean arterial pressure. In patients with initial normal levels, no further decrease of blood pressure or reflex tachycardia occurred. Abrams[2] and Chiche et al[14] demonstrated that nitrates may reduce systemic vascular resistance only if it is initially elevated.

Rabinowitz et al[8] showed a relation between high systemic vascular resistance, tachycardia and elevated levels of circulating cathecholamines in response to low cardiac output. Initial systemic vascular resistance levels may predict the response to nitrate therapy: Cardiac output increases in patients with high initial systemic vascular resistance. Our dates with IS-5-MN demonstrate beneficial effects in patients with elevated blood pressure.

Our study showed that IS-5-MN caused no adverse decrease of blood pressure. A temporary decrease was due to morphine and mechanical ventilation, and was

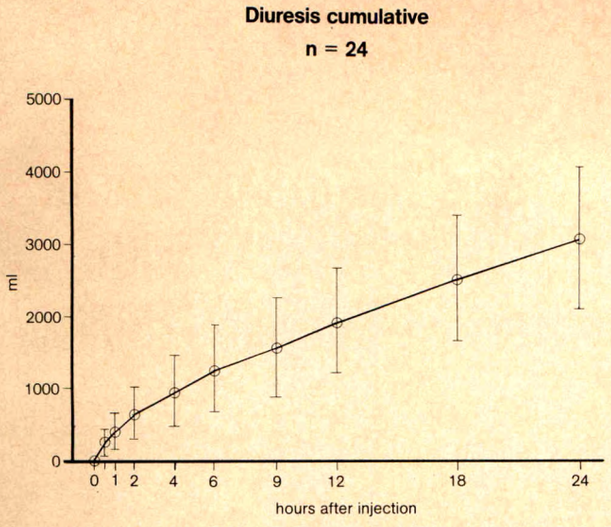

FIGURE 9. Cumulative diuresis over the 24-hour study period.

reversible after less than 1 hour. A marked diuresis with rapid onset of urine flow and negative fluid balance occurred in all patients, many of them having been unresponsive to diuretic therapy before IS-5-MN. ISDN has been shown to increase significantly effective renal perfusion in acute heart failure with a proved synergistic effect with furosemide.[17]

As an open study, conclusions must be limited because of lack of control data. Otherwise, from the ethical point of view, the performance of placebo-controlled studies in such severe ill patients is impossible. In an open hemodynamic trial with i.v. IS-5-MN, Gammage et al[16] demonstrated a rapid decrease of pulmonary capillary pressure associated with symptomatic relief and the lack of other adverse changes, particularly a significant decrease in blood pressure. This confirms that IS-5-MN may be given safely by this route of administration without hemodynamic monitoring.

Conclusions

Intravenous IS-5-MN is effective and safe in the management of acute pulmonary edema, without significant risk of adverse circulatory effects, provided there is close clinical monitoring, particularly regular control of heart rate and blood pressure.

Dose-Ranging Study of Isosorbide-5-Mononitrate in Chronic Congestive Heart Failure Treated with Diuretics and Angiotensin-Converting Enzyme Inhibitor

NADIA DEBBAS, MD, DAVID WOODINGS, MRCP, CHRISTINE MARKS, ANGELA BHANS, MBBS, AKEEL JUBBER, MRCP, IAN DEWS, MRCP, JOHN STEPHENS, MD, MRCP, and MALCOLM VANDENBURG, BSc, MRCP

The hemodynamic response of isosorbide-5-mononitrate (IS-5-MN) to the addition of the widely used therapy of diuretic drugs and the maximally tolerated dose of enalapril for heart failure was assessed in 8 patients with congestive heart failure (CHF) (New York Heart Association class II and III). The diuretic therapy was furosemide, 40 to 80 mg/day, with or without amiloride, 5 to 10 mg/day. The dose of enalapril was 5 to 20 mg/day. Four hours after the administration of the morning dose of enalapril, a Swan-Ganz catheter was positioned in the pulmonary artery. Patients received increasing doses of IS-5-MN to produce a satisfactory decrease in pulmonary capillary wedge pressure. Two of the first 3 patients studied had a large reduction in blood pressure when given 10 mg of IS-5-MN. Subsequent patients were therefore given an initial dose of 5 mg, the total dose being 5 to 20 mg over 2 hours. Results at baseline and 1 hour after the final dose of IS-5-MN are expressed as mean ± standard deviation. Both pulmonary artery systolic and diastolic pressures decreased significantly ($p < 0.05$) by 12.2 ± 8.9/4.2 ± 5.2 mm Hg, from 47.2 ± 16.0/21.6 ± 6.0 mm Hg to 35.0 ± 15.2/17.4 ± 9.3 mm Hg. Pulmonary capillary wedge pressure decreased by 8.6 ± 4.4 mm Hg, from 22.1 ± 5.4 to 13.6 ± 7.5 mm Hg ($p < 0.01$). There was a significant ($p < 0.05$) decrease in both systolic and diastolic blood pressures of 18.0/9.1 mm Hg, from 111.2 ± 24.5/72.6 ± 4.9 to 93.2 ± 22.1/63.5 ± 8.7 mm Hg. There was no change in heart rate, right atrial pressure and cardiac output.

The results suggest that IS-5-MN produces beneficial hemodynamic effects when added to diuretics and angiotensin-converting enzyme inhibitors. The doses used are lower than when IS-5-MN is added to the diuretic alone.

(Am J Cardiol 1988;61:28E–30E)

Diuretics are widely used as first line treatment of chronic congestive heart failure (CHF). When additional therapy is necessary, the beneficial effect of nitrates is well established.[1] Recently, angiotensin-converting enzyme inhibitors have been used as second line treatment in addition to diuretics.[2]

Oral isosorbide dinitrate has generally been used in patients receiving diuretics plus another additional therapy, with or without digitalis, as a further stage of treatment. However large doses are often required to achieve suitable beneficial effect, although tolerance has not yet been documented even at large doses.[3,4] Isosorbide-5-mononitrate (IS-5-MN), an active metabolite of isosorbide dinitrate, has a similar hemodynamic profile in patients with chronic CHF and may be more potent.[5]

The purpose of this study is to define the dose response in hemodynamic changes in patients with CHF when IS-5-MN is added to their treatment with the angiotensin-converting enzyme inhibitor, enalapril.

receiving a stable dose of diuretics: furosemide, 40 mg/day (n = 6) and 80 mg/day (n = 2) with or without amiloride 5 mg/day (n = 4) and 10 mg/day (n = 1). They also were taking the maximal tolerated dose of enalapril, 5 to 20 mg/day (5 mg in 1, 10 mg in 3, 15 mg in 1 and 20 mg in 3 patients). Before entering the study, all patients gave informed written consent.

All medications were taken normally until the day of the study when the diuretic was omitted. Four hours after the morning dose of enalapril was administered, hemodynamic evaluation was performed by Swan-Ganz catheterization. Measurements were obtained from midchest level. Baseline measurements of heart rate, systolic and diastolic pulmonary artery, pulmonary capillary wedge and mean right atrial pressures and cardiac output in triplicate using the thermodilution method were obtained. Having confirmed hemodynamic stability, and provided that pulmonary capillary wedge pressure was >16 mm Hg, increasing doses of oral IS-5-MN were given to reduce pulmonary capillary wedge pressure to between 12 and 15 mm Hg.

In the first 3 patients studied, an initial dose of 10 mg was given, followed 60 minutes later by hemodynamic evaluation. In the next 5 patients, the initial dose of IS-5-MN was 5 mg. If systolic blood pressure was maintained at >90 mm Hg and left ventricular filling pressure at >12 mm Hg 60 minutes after dose evaluation, further doses of 5 mg were administered if necessary. Hemodynamic status was assessed 60 minutes after each dose.

Mean values and standard deviation were calculated for each parameter before, 1 hour after the first dose and 1 and 2 hours after the last dose of IS-5-MN was administered. Student paired *t* test was used to compare baseline values with the values at 1 hour after the first dose and 1 and 2 hours after the last dose of IS-5-MN for each variable.

Results

Two of the first 3 patients who received 10 mg of IS-5-MN as an initial dose had a reduction in systolic blood pressure to 60 mm Hg. The third patient had a satisfactory hemodynamic response 1 hour after receiving an additional dose of 10 mg of IS-5-MN (cumulative dose 20 mg). Three of the 5 remaining patients received 5 mg of IS-5-MN, 1 patient received additional doses to a cumulative dose of 15 mg, and 1 patient received additional doses to a cumulative dose of 20 mg. All patients responded over 4 hours. Both systolic and diastolic pressures decreased significantly by 10.8 and 4.4 mm Hg, respectively, between baseline and 1 hour after the first dose of IS-5-MN (Table I) and remained low at 1 and 2 hours after the last dose (Fig. 1). Pulmonary capillary wedge pressure decreased by 9.2 mm Hg 1 hour after the first dose and also remained low at 1 and 2 hours after the last dose. The same type of response was observed for systolic and diastolic pressures, with a decrease of 18.0 and 9.1 mm Hg 1 hour after the last dose of IS-5-MN was administered. There was no change in heart rate, right atrial pressure and cardiac output (Fig. 1).

Discussion

IS-5-MN is a metabolite of isosorbide dinitrate. Unlike the latter, which undergoes considerable biotransformation by the liver and possibly by the gut, IS-5-MN is completely bioavailable.[6] Stephens et al[5] found that acute oral IS-5-MN given to patients with CHF taking diuretics alone has beneficial effects on left ventricular performance through reduction in preload. In the present study, the acute effect of IS-5-MN added to diuretic therapy plus maximal tolerated dose of enalapril was similar, reducing the preload but also decreasing systemic arterial pressures.

In our experience, when patients were taking diuretics plus enalapril, after 3 attempts with initial doses of 10 mg of IS-5-MN, 2 patients had severe hypotension requiring reduction of the first dose. However, in the report by Stephens et al,[5] the doses used to achieve satisfactory hemodynamic changes in patients taking diuretics alone varied between 20 and 100 mg of IS-5-MN, the initial dose being 20 mg. Therefore, the full dose received by our patients was about 20 to 25% of that used in studies where an angiotensin-converting enzyme inhibitor was not part of the successful treatment. This suggests that patients receiving enalapril in addition to diuretics have an increased sensitivity to the vasodilator effect of IS-5-MN and therefore lower doses of the latter should be used. However this reaction seems to be a first-dose effect. We would therefore suggest that 5 mg would be a correct starting dose in this circumstance and that until absolute safety of this dose has been evaluated, it would be appropriate for patients to be kept under medical supervision for at least 4 hours.

Although there is doubt concerning the long-term efficacy of nitrates in patients with angina because of tolerance,[7] there is evidence that tolerance does not develop during long-term treatment with isosorbide dinitrate in patients with CHF[3,4]; the results of previous studies indicate that the same is true for IS-5-MN.[5] However a long-term double-blind study under the same conditions as the present one is still needed to confirm the benefits seen in this pilot study.

Acute Effect of Various Doses of Isosorbide-5-Mononitrate on Hemodynamic and Exercise Performance in Coronary Artery Disease

WOLFGANG JANSEN, MD, LEONHARD MEYER, MD, and MICHAEL TAUCHERT, MD

The optimal dose of nitrates is still controversial, as chronic usage of too high a dose may result in a decrease in vascular response. The dose should be determined to reduce preload acutely, and not to decrease the activity during chronic therapy. To determine this dose, 50 patients with angiographically confirmed coronary artery disease were studied. The effects on heart rate and mean systemic and pulmonary arterial pressures at rest and during exercise, and work capacity and duration were measured. The patients were classified into 5 groups, receiving placebo or isosorbide-5-mononitrate, 5, 10, 20 and 50 mg, respectively, as a single oral dose. Placebo had no effect on the measured parameters. All doses of isosorbide-5-mononitrate reduced mean pulmonary arterial pressure: 10 mg—by 16% at rest and 24% during exercise; 20 mg—24% and 34%, respectively (a near maximal effect); and 50 mg—27% and 38%. Similar results were found also for work capacity: 10 mg increased work capacity by 33%; 20 mg—79%; and 50 mg—56%. Thus, the therapeutically optimal single dose is about 20 mg. Higher doses produce no additional benefit and increase the risk for tolerance development.

(Am J Cardiol 1988;61:31E–35E)

The accurate dose of either isosorbide dinitrate (ISDN) or isosorbide-5-mononitrate (IS-5-MN) optimally affecting both hemodynamics and exercise performance is not known.[1–5] The possibility of development of tolerance to nitrates due to use of high doses indicates that these drugs should be given at a dose sufficient to produce their therapeutic effect but at a lower dose than that causing tolerance. Dietmann et al[6] demonstrated with animal studies, a linear relation between the nitrate dose, mean plasma concentration and the extent of reducing systolic blood pressure. These findings indicate that it is possible to determine the quantitative relations between the dose of IS-5-MN and its effect. This study determines the acute effect of various doses of IS-5-MN on hemodynamics and exercise performance of patients with coronary artery disease.

Methods

Fifty patients, aged 29 to 66 years (mean 52.1 ± 7.8), with angiographically demonstrated coronary artery disease were studied. All gave signed informed consent. Patients with clinical or radiographic signs of congestive heart failure, large aneurysms, pulmonary diseases, serious arrhythmias or crescendo angina were excluded from the study. All cardioactive drugs were withdrawn at least 72 hours before the trial and sublingual nitroglycerin was not allowed 6 hours before the trial.

The patients were hospitalized in the coronary care unit and a Swan-Ganz catheter was introduced. To prevent the effect of circadian variations,[7] all measurements were obtained at the same hour (in the early afternoon) each day. Hemodynamic measurements were performed at rest. Supine bicycle exercise test was performed and the exercise duration and capacity (product of exercise time in minutes and load in Watts) were determined. The test was symptom-limited, and was discontinued when pulmonary arterial pressure reached 60 mm Hg or more or when ischemic electrocardiographic changes developed in asymptomatic patients.

Abbreviations as in Table I.

When the heart rate and blood pressure returned to baseline, the patients were allowed to rest and received the following treatment: group 1—placebo (8 patients, aged 47 ± 10.7 years); group 2—IS-5-MN, 5 mg orally (10 patients, aged 54.9 ± 6.2 years); group 3—IS-5-MN, 10 mg orally (10 patients, aged 55.8 ± 5.7 years); group 4—IS-5-MN 20 mg orally (11 patients, aged 50.9 ± 8.2 years); and group 5—IS-5-MN, 50 mg orally (11 patients, aged 51.2 ± 6.0 years). The hemodynamic measurements were repeated at 45 minutes after drug administration and the exercise test was also repeated.

Student *t* test was used for evaluation of statistical significance of the results at $p < 0.05$.

Results

All patients completed the study without complications. Results are presented in Tables I and II and Figures 1 to 3.

Heart rate: Heart rate was not altered at rest. During exercise it was not altered with placebo and IS-5-MN, 5 mg, but decreased slightly but significantly with 10, 20 and 50 mg (at comparable workload).

Mean arterial pressure: Placebo and IS-5-MN, 5 mg, did not alter mean arterial pressure. The other doses decreased this parameter slightly but significantly.

Mean pulmonary arterial pressure: Placebo did not alter this parameter at rest or during exercise. All doses of IS-5-MN reduced it in a dose-dependent manner: at rest—5 mg 17%, 10 mg 16%, 20 mg 24%, and 50 mg 27%; during exercise—5 mg 10%, 10 mg 24%, 20 mg 34%, and 50 mg 38%. All changes were significant (Fig. 1).

Work capacity: Placebo and IS-5-MN, 5 mg, did not significantly alter work capacity. After 10, 20 and 50 mg, work capacity significantly increased. After administration of 10 mg, work capacity increased from 315 ± 119 to 418 ± 153 W·min. Seven of the patients in this group increased their work capacity by 75 W·min. Only 3 patients showed only slight increase or no increase at all. After administration of 20 mg, work capacity significantly increased from 293 ± 142 to 524 ± 244 W·min. Only 1 patient did not show an increase in work capacity with this dose. After administration of 50 mg, work capacity significantly increased from 316

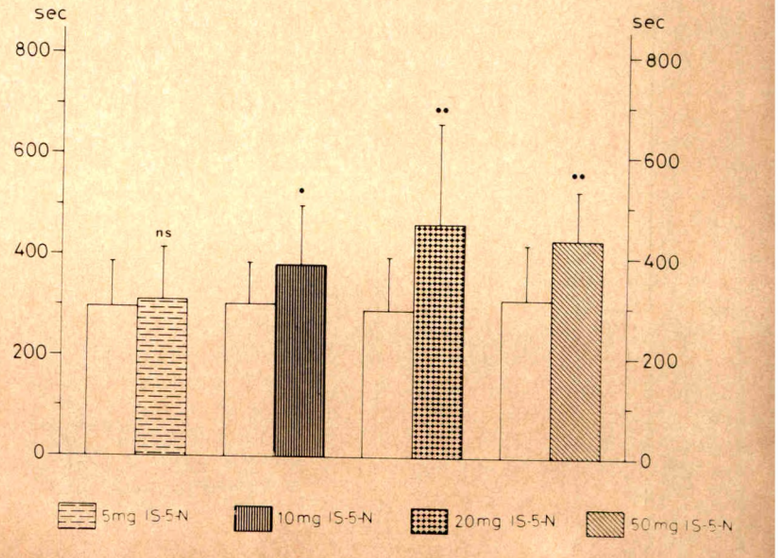

FIGURE 2. Work duration before (*open bars*) and after various oral doses of isosorbide-5-mononitrate (IS-5-MN). • p = 0.05; •• p = 0.01; ns = not significant.

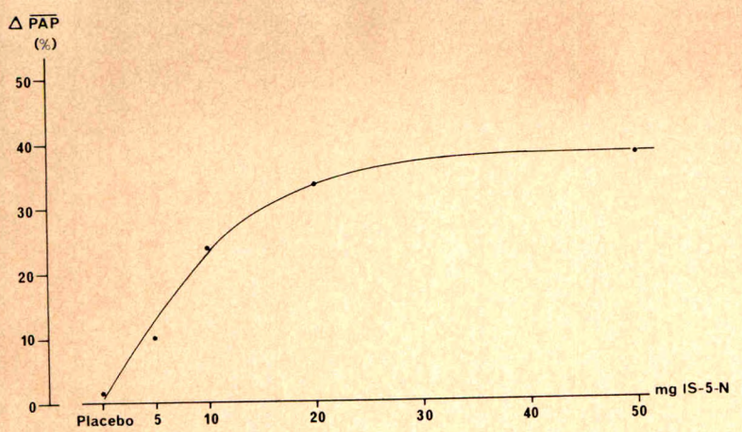

FIGURE 3. Relation of hemodynamic response to dose of isosorbide-5-mononitrate (IS-5-MN). *Ordinates*, percent decrease in mean pulmonary arterial pressure (Δ PAP) during exercise (50 W/3 min). *Abscissa*, dose of IS-5 MN.

± 149 to 493 ± 151 W·min. Only 2 patients had no improvement.

Exercise duration: Placebo and IS-5-MN, 5 mg, did not alter exercise duration. After administration of 10 mg, exercise duration significantly increased from 304 ± 93 to 381 ± 118 seconds (25%); after 20 mg, from 289 ± 106 to 466 ± 197 seconds (61%); and after 50 mg, from 308 ± 105 to 428 ± 95 seconds (39%) (Fig. 2).

Discussion

ISDN has been used for about 20 years for treatment of coronary artery disease, with proved efficacy.[8,9] Determination of dose-effect relations is complicated by the first-pass hepatic metabolism and the variability in absorption (at least with slow-release formulations).[10-12] IS-5-MN, a metabolite of ISDN is effective in coronary artery disease and has the advantages of complete absorption, lack of first-pass hepatic metabolism and pharmacodynamic half-life of 5 hours.[2,4,13-18] Therefore, it is more suitable for prolonged treatment than the parent drug ISDN.

Studies of tolerance development with chronic administration of high doses of nitrates revealed that the dose chosen should be the lowest that is still effective.[19-25] Our study has attempted to determine this dose for IS-5-MN. Systemic arterial pressure is not an adequate parameter to determine dose-response relations for nitrates, as was shown by another study from our group.[26] A better parameter is mean pulmonary arterial pressure, which directly correlates with the preload—the main target for the effect of nitrates—and which can be measured reproducibly.[27] We demonstrated significant and dose-dependent reductions of mean pulmonary arterial pressure with IS-5-MN, at doses of 5 mg or more, the optimal dose being 20 mg (Fig. 3). Single doses of more than 20 mg did not produce any additional benefit. Similar results were obtained in another study by our group, in patients undergoing cardiac catheterization.[26] Also, 5 mg is the initial effective dose and 20 mg the optimal dose for work capacity and duration. Single doses of 50 mg are not more effective than single doses of 20 mg. These results confirm those of Abshagen and Spörl-Radun,[13] demonstrating that an increase in dose to 50 mg produced a slight decrease in therapeutic parameters despite an increase in plasma level.

In conclusion (1) the initial oral dose level of IS-5-MN is 5 mg; (2) the hemodynamic and antianginal (demonstrated by work capacity) effect of a single dose of 10 mg is smaller than that of 20 mg; (3) the optimal effect is achieved with a single dose of 20 mg; and (4) it is preferable not to use doses higher than 20 mg because they do not have an additional therapeutic benefit and may be expected to produce tolerance.[14,28]

Transdermal Nitroglycerin Patches for Silent Myocardial Ischemia During Antianginal Treatment

ADAM SCHNEEWEISS, MD, and ALON MARMOR, MD

Because silent ischemia is not associated with an increase in heart rate and, being asymptomatic, its treatment requires constant therapeutic plasma levels of the drug used, a transdermal nitroglycerin patch (Deponit®) was selected for treatment of this condition. Eight patients with documented silent ischemia were studied. All patients also had angina on effort treated with calcium antagonists (n = 8) and β blockers (n = 6). They were evaluated by 24-hour ambulatory electrocardiographic monitoring. The transdermal nitroglycerin patch, 20 to 30 mg/24 hours, reduced the number of silent ischemic episodes from 9.25 ± 5.52 to 2.4 ± 2.0 episodes per 24 hours ($p < 0.001$). The maximal ST-segment depression was reduced from 3.1 ± 0.7 to 0.9 ± 0.7 mm ($p < 0.001$). Ventricular premature beats were significantly reduced, by 50%. Symptomatic ischemic episodes were completely suppressed. Thus, transdermal nitroglycerin, in moderate doses, is effective in suppressing silent ischemia in patients with angina pectoris who have silent ischemic episodes despite treatment with other antianginal agents.

(Am J Cardiol 1988;61:36E–38E)

Recently it has been shown that silent myocardial ischemia, not accompanied by chest pain, dyspnea or cardiac arrhythmias occurs more frequently than symptomatic myocardial ischemia.[1,2] Silent myocardial ischemia adversely affects prognosis.[3-5] This justifies treatment to suppress the ischemia, although it has not been shown that such treatment improves prognosis.

Most episodes of silent ischemia are not preceded by an increase of major determinants of myocardial oxygen demand such as heart rate or systemic arterial pressure.[2,6] This finding indicates that β blockers would not be very effective in silent ischemia. Nitrates should be theoretically more useful.

Because the condition is asymptomatic, the most rational approach would be to maintain a constant therapeutic level of the drug in the plasma. Transdermal nitroglycerin patches are optimal for this purpose.[7] This report describes our experience with suppression of silent myocardial ischemia by transdermal nitroglycerin patch (Deponit® 10).

Methods

Eight men, mean age 65.5 ± 12.0 years, were studied. All had chronic stable angina pectoris on effort, with exercise-induced ST-segment depression of ≥2 mm. One had recurrent syncope. One patient had undergone percutaneous transluminal coronary angioplasty and 1 coronary artery bypass surgery >1 year before the study. Results of a 12-lead electrocardiogram were normal in 7 patients and showed flattening of the T wave in 1. All patients were treated with nifedipine, 30 to 60 mg/day, and 6 of them also received propranolol, 80 to 160 mg/day, or atenolol, 100 mg/day. All were also using sublingual nitroglycerin. Ambulatory 24-hour electrocardiographic monitoring was performed using the Marquette system and a computerized ST-segment analyzer. Significant ST-segment depression was defined as the horizontal or downsloping shift of ≥1 mm, occurring for ≥80 ms after the end of the QRS complex, ≥1 minute in duration.

During the first study the patients received their usual antianginal treatment, except for sublingual nitroglycerin. Within 7 days, patients underwent another study, starting 1 hour after application of transdermal nitroglycerin (Deponit 10), 30 mg. After 1 hour, 2 patients had a reduction in dosage to 20 mg—1 because of hypotension and the other because of headache. The patients were instructed to record the time of anginal episodes. The paired *t* test was used to evaluate significance.

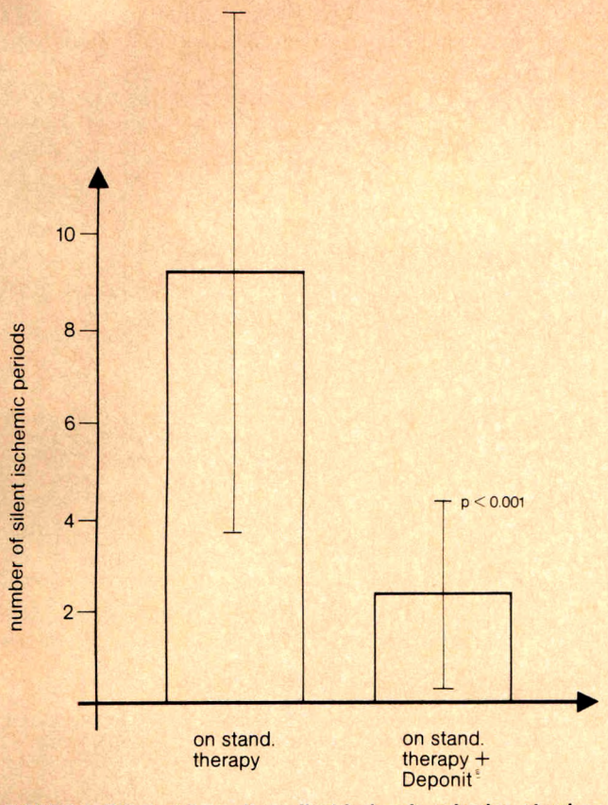

FIGURE 1. Effect of Deponit on silent ischemic episodes. stand. = standing.

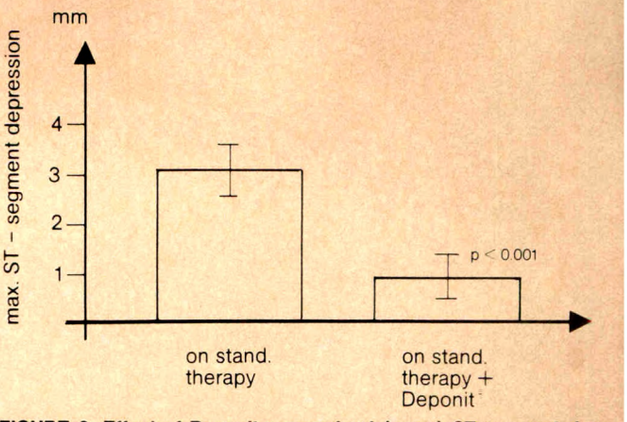

FIGURE 2. Effect of Deponit on maximal (max.) ST-segment depression. stand. = standing.

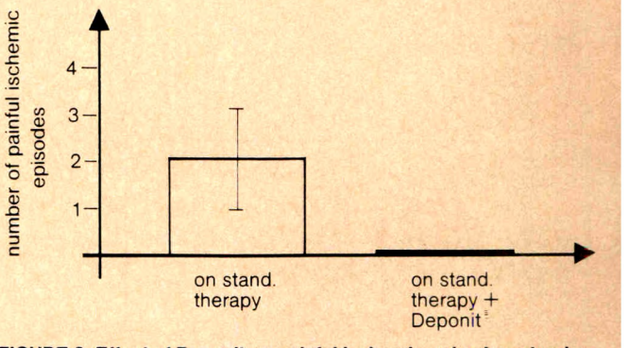

FIGURE 3. Effect of Deponit on painful ischemic episodes. stand. = standing.

Results

All patients completed the study. Treatment with transdermal nitroglycerin resulted in a decrease of silent ischemic episodes from 9.25 ± 5.52 to 2.4 ± 2.0/24 hours ($p < 0.001$) (Fig. 1). The maximal ST-segment depression was reduced from 3.1 ± 0.7 to 0.9 ± 0.7 mm ($p < 0.001$) (Fig. 2). The number of painful ischemic episodes was reduced from 2.1 ± 1.1/day to 0 (Fig. 3). The number of premature ventricular beats was reduced from 243 ± 149 to 121 ± 106/day ($p < 0.05$) (Fig. 4). Runs of ventricular tachycardia were observed in 3 patients without transdermal nitroglycerin and in no patient taking this drug. The frequency of couplets was slightly but nonsignificantly reduced. Adverse effects included hypotension in 1 patient (which responded to reduction in dose) and headache in 3.

Discussion

Our findings indicate that transdermal nitroglycerin (in the form of Deponit) is very effective in suppression of silent myocardial ischemia. The drug was effective in all patients studied. The fact that all patients had silent ischemia while taking various antianginal agents, other than nitrates, was of interest. The addition of transdermal nitroglycerin to this regimen suppressed the silent ischemic episodes.

Several previous studies suggest that nitrates and other antianginal agents are effective in relieving silent ischemia and its consequences. Pepine et al[8] showed that intravenous administration of nitroglycerin reversed asymptomatic episodes of left ventricular dyskinesia attributed to silent ischemia. Glazier et al[9] reported that atenolol is effective in reducing both angina and silent ischemic events in patients with both mixed angina pectoris and silent ischemia. These investigators suggested that in mixed angina, β blockers probably act by reducing the basal metabolic requirements of the heart, thereby making transient reductions in coronary blood flow less likely to reach a critical ischemic level. Perhaps the most important finding of our study is that the patients had silent ischemia despite antianginal therapy (other than nitrates). These episodes were suppressed by nitroglycerin. This may be attributed to the different pathophysiology of painful and silent myocardial ischemia. Selwyn et al[10] studied the myocardial perfusion by positron emission tomography in patients with both painful and silent ischemic episodes. In all their patients, both painful and silent ischemic episodes showed equal decreases in myocardial perfusion. However, angina occurred only when this ischemic insult was enhanced by sufficient increase in myocardial oxygen demand. These findings indicate that impaired perfusion is the primary mechanism of silent ischemia and drug therapy should be directed at improving perfusion rather than reducing myocardial oxygen demand.

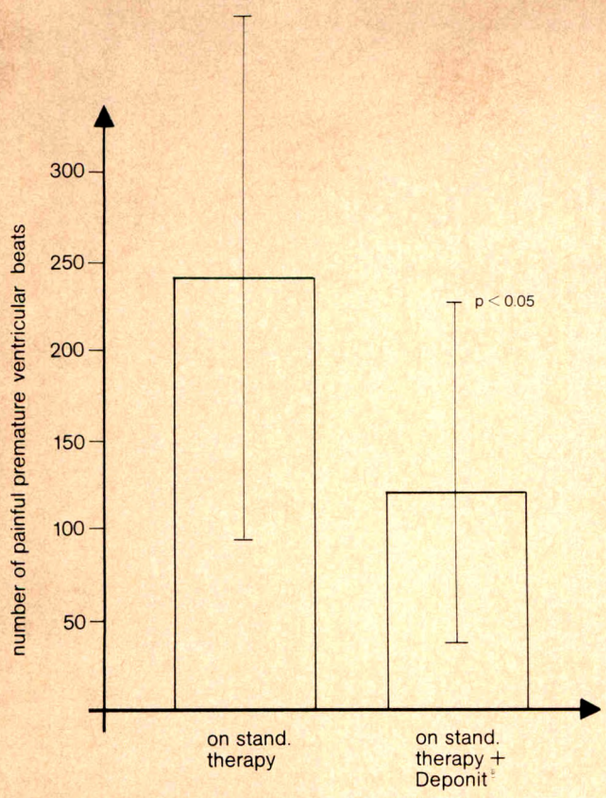

FIGURE 4. Effect of Deponit on premature ventricular beats. stand. = standing.

Another interesting finding was the partial suppression of ventricular premature beats. Myocardial ischemia can be expressed as arrhythmias, and antiischemic agents may thus have an antiarrhythmic effect. Nitrates were shown to possess indirect antiarrhythmic properties in patients with coronary artery disease.[11,12] This activity may be useful in patients with silent ischemia whose episodes are associated with arrhythmias and syncope.

In summary, transdermal nitroglycerin was found very effective in preventing silent myocardial ischemia in patients with angina pectoris who had silent ischemic episodes despite antianginal treatment (other than long-acting nitrates).

Acute and Sustained Antianginal Effects of Nitroglycerin Patches: Objective Evaluation with Training-Effect-Eliminated Exercise Performance Index

HASAN DOGAR, MD, DENIZ GÜZELSOY, MD, NAZMI GÜLTEKIN, MD, NILGÜN GÜRSES, PhD, and CEM'I DEMIROGLU, MD

A randomized within-patient double-blind acute and sustained study was performed to compare transdermal nitroglycerin (NTG) patches (5 and 10 mg) and matching placebo in 10 patients with chronic stable angina pectoris confirmed on exercise thallium scintigraphy or coronary angiography, or both. Patients performed treadmill tests 2 and 24 hours after application of patches on the first and last days of each of the 3 treatment periods. Effects caused by sequence of treatments and training with serial testing were prominent so the changes in the well-known parameters did not favor either of the active doses over placebo. Quantification of training effects and its subtraction from performance index disclosed that 10 mg of transdermal NTG caused significant increase in performance in both the acute and sustained stages of therapy in comparison to pretreatment performance. This was not observed with 5 mg and placebo treatments.

To our knowledge, this is the first trial to study the efficacy of transdermal NTG with a more objective parameter that permitted elimination of training effects of serial exercise testing.

(Am J Cardiol 1988;61:39E–43E)

Now in its second century of clinical use, nitroglycerin (NTG) is a mainstay of antianginal therapy, and innovative delivery systems have extended the use of it beyond the painful attack.[1] The most recent system works transcutaneously, with daily applied patches releasing NTG at a constant rate over at least 24 hours.[2] NTG plasma levels are dose-dependent, and steady-state plasma levels are reached within 2 hours and maintained for at least 24 hours.[1,3] The present study was designed to assess the efficacy of 2 different doses of a transdermal NTG preparation (Deponit®, Schwarz GmbH) in the prophylaxis of angina pectoris during an acute and sustained study.

Methods

Eight men and 2 women, aged 41 to 64 years (average 52), with chronic stable angina pectoris were studied. The diagnosis of coronary artery disease was confirmed by exercise thallium scintigraphy (n = 9) or arteriographic demonstration of significant luminal narrowing (>70%) of at least 1 major coronary artery (n = 5), or both. Each patient had typical exertional angina and had chest pain during treadmill exercise testing, with a positive test result showing at least 1 mm of horizontal or downsloping ST-segment depression that lasted for at least 80 ms after the J point. No patient had cardiomegaly, congestive heart failure, serious hepatic or renal disease, hypertension, serious conduction disturbances or arrhythmias, diabetes mellitus, anemia, unstable angina or a myocardial infarction within the preceding 3 months. No patient was given digitalis or diuretic or antianginal drugs other than sublingual NTG for the 2 weeks before and during this investigation. All patients gave informed consent for the study.

A randomized within-patient double-blind acute and sustained study, comparing the transdermal NTG patches releasing 5 mg (1 active, 16-cm^2 patch containing 16 mg NTG and a matching placebo patch), 10 mg (2 active patches) and 0 mg (2 placebo patches) over 24 hours, was planned. Patients performed a preliminary symptom-limited treadmill test, which was stopped

because of typical angina of moderate severity and horizontal or downsloping ST-segment depression >1 mm and was repeated to judge reproducibility. Of these 2 tests, the one with longer duration of exercise was accepted as the pretreatment test (test I). Patches were mixed after being coded beforehand; thus the sequence of the treatments were taken at random. They were applied to a hairless part of the chest wall every 24 hours for 15 days during each of the 3 treatment periods, which were separated by an interval of 2 or 3 days. During treatments, exercise tests were performed 2 (test II) and 24 (test III) hours after the application of the patches on the first day, and again 2 (test IV) and 24 (test V) hours after the application on the 15th day of each treatment.

Treadmill tests were performed under the same conditions according to the Bruce protocol. Tests II and III were stopped at the end of the same walking time of test I, while tests IV and V were symptom-limited with conventional endpoints.

A 12-lead electrocardiogram was recorded at rest and at every minute during the test and during the 5-minute recovery period. Three leads (V_2, V_4 and V_6) were monitored throughout the test.

Blood pressure was measured with a mercury sphygmomanometer. Heart rate was measured from the electrocardiogram.

The performance index (PI) was calculated from a previously devised formula[4]:

$$PI = t/(PSBP \cdot PHR \cdot 10^{-2})$$

where t = time on treadmill in seconds; PSBP = peak systolic blood pressure; and PHR = peak heart rate.

By eliminating the training effect (TE) of serial exercise testing, corrected PI (PI_c) was obtained, and PI_c was used as an objective parameter in comparing pretreatment performance with performance during each of tests II through V of all the 3 treatments:

$$PI_c = PI - (TE \cdot m)$$

where m = the number of tests a patient had performed between test I and the test in question.

TE is a constant that may be estimated for any trial form:

$$TE = (\Sigma x_p - \Sigma x_i)/n$$

where Σx_p = sum of the PI values calculated in a group of tests at a late control or placebo phase of treatment; Σx_i = sum of the PI values obtained in the pretreatment tests; and n = number of all tests—including those under any treatment—between the pretreatment and the late control tests in all subjects.

In this study, the increase in PI between test II of the placebo phase and test I was taken into account in the calculation of PI_c. One preliminary test was attributed to the familiarity effect and was not included in the evaluation of m.

Student *t* test for paired data was used to assess the statistical significance of differences between pretreatment performance and performance during therapy. Differences were considered significant at $p < 0.05$.

Results

All 10 patients completed the 3 treatments of the study. Two patients had mild headaches for the first 2 days of treatment with active doses. One also had headache with placebo. No other adverse effect was observed.

Analyses of the changes in blood pressure and heart rate at rest, exercise duration, time to development of 1-mm of ST-segment depression, degree of ST-segment depression, peak heart rate, peak systolic blood pressure and double product did not show any significant difference between either of the active doses and placebo in their comparison with pretreatment values. Frequency of anginal attacks and the use of sublingual NTG decreased in 2, 7 and 8 patients receiving treatment with placebo, 5 mg and 10 mg, respectively.

Because effects caused by sequence of treatments and training with serial treadmill exercise testing were prominent, as clearly seen in the mean PI values of the placebo phase, which happened to be the third treatment in more than half of patients, PI_c was devised for the elimination of these effects. Training effect was quantified in reference to the difference of performance between test I and II of the placebo phase, which yielded an optimal constant (0.08 per test), with a much lower value than that estimated from test V of the placebo phase (0.13 per test).

PI in test I and the PI, PI_c and m values in all the treatments in 10 patients are given in Table I. Mean PI (± standard deviation) and mean PI_c (± standard deviation) are shown in Table II. Three of 4 mean PI values obtained with placebo were higher than those with the active doses. In terms of PI_c, however, a significant increase in performance was found at the second hour of application of both the active doses on the first day (acute study period) compared with pretreatment and placebo values. At the 24th hour of acute therapy and at the second and 24th hours on the 15th day (sustained therapy), mean PI_c values with 10-mg patches were significantly higher than mean PI during pretreatment, although not significantly different from those of the placebo and 5-mg treatments.

Although some mean PI_c values with placebo and 5-mg treatments were higher than that calculated in test II of the 10-mg treatment, they were not significantly different from the pretreatment PI, because the statistical analysis was based on paired data, which compared the variations within each patient.

Discussion

Since its introduction in 1981 as a new approach to prolonging nitrate action, transdermal NTG delivery system has gained wide acceptance in the clinical community. Recently, however, questions have arisen regarding the efficacy of transdermal patches in the prevention of anginal attacks in coronary artery disease.[5-7] Nevertheless, many factors (e.g., protocol and design, the subjects chosen, and even the physicians conducting the clinical trials) are challenged.[8] In fact, the Food and Drug Administration developed criteria

for assessing the effectiveness of antianginal agents by comparing pretreatment performance with performance during therapy at symptom-limited treadmill exercise testing.[8,9]

The accurate evaluation of clinical efficacy of an antianginal drug is fraught with difficulties when subjective parameters, such as changes in incidence of anginal attacks and NTG consumption,[10] and objective indexes of effort-induced myocardial ischemia, such as ST-segment depression, workload, time on treadmill, heart rate and blood pressure responses,[4] are used. Many studies evaluating the efficacy of transdermal NTG using these parameters have been performed, and the results and reasons for inconsistencies are reviewed elsewhere.[2,11,12] Perhaps the most difficult question remains: What measure of efficacy is clinically most relevant?[2] The number of patients, on the other hand, was exceedingly small in all of these acute (average 10 patients) or sustained (14.6 patients) studies,[2] and a unique multicenter large trial with NTG patches is still in progress in conjunction with the Food and Drug Administration, academic community and industry.

With respect to design, this trial resembles most of the trials including short- and long-term therapy. Every effort was made to standardize the conditions of the exercise tests. In terms of the aforementioned parameters, however, statistical significance was not achieved against placebo, and numerical results were not given, although they appeared to have clinical significance against pretreatment values. It has been recently demonstrated that placebo, in a single- or double-blind protocol, does not affect the objective indexes of effort-induced myocardial ischemia[10]; however, the reverse may be true in such a trial as this, in which every patient underwent at least 14 exercise tests in less than 2 months. Then, the improvement in the indexes during the placebo therapy should have been due to the placebo effect and to the familiarity and training effects with repeated exercise testing, the latter not being dealt with or sufficiently detailed in most published studies.[2]

This assumption led us to the tentative quantification of TE by using the PI that has recently been proposed by Miller and Grais.[4] The reasons for choosing this index were: (1) It included, in itself, 3 indexes as components of performance; and (2) as one would expect, it reflects the effects of physical training very well.[4] Also, because of its latter property, the analysis of differences in raw PI values obtained during each of the 3 treatments did not result in statistical significance. When we assumed that a factor that can be subtracted from all PI values obtained in all the tests during treatments would eliminate TE, an optimal constant was estimated to represent TE for every test in this study group. Surprisingly, the analysis of differences in terms of PI_c, which was obtained by the reduction of PI as defined in the Methods section, resulted in statistical significance proving the efficacy of 5 and 10 mg of transdermal NTG 2 hours after application in acute therapy compared with placebo and pretreatment control. It also demonstrated the efficacy of 10 mg of transdermal NTG 24 hours after application in acute therapy and 2 and 24 hours after the last application in sustained therapy compared with pretreatment performance; however, PI_c of placebo and 5 mg of transdermal NTG at these instances were not statistically significant from pretreatment performance.

This outcome may explain the inconsistencies within those "negative" trials[5,13] of transdermal NTG in which results appeared to have clinical significance (quantitative increase), yet statistical significance was not achieved.

Even after the subtraction of TE, average performance with placebo and 5 mg showed improvement, although statistically not significant. In the case of the placebo treatment, this may be due to the prominent placebo effect in some patients and supports the idea that new antianginal drugs should be compared with drugs of established antianginal efficacy, rather than with placebo periods.[5] With 5-mg treatment, it might be due to the marked individual variability in NTG sensitivity (i.e., some nitrate-responsive patients may truly derive a real benefit from low-dose transdermal NTG).[6]

In conclusion, this study, representing the first to exclude the training effects in exercise testing, demonstrates that transdermal NTG patches releasing 10 mg are effective in improving the exertional performance in a group of patients with coronary artery disease for a period of 15 days.

Efficacy of a New Transdermal Nitroglycerin Patch (Deponit 10) for Stable Angina Pectoris

RAFFAELE GRECO, MD, DORIANA D'ALTERIO, MD, MARIO SCHIATTARELLA, MD, ANGELO BOCCIA, MD, LUIGI GRECO, MD, and FEDERICO MARSICO, MD

In this double-blind randomized placebo-controlled crossover study, the antianginal and anti-ischemic effect of a new transdermal system, releasing 10 mg of nitroglycerin (NTG) over 24 hours, was assessed in 19 outpatients with stable exercise-induced angina pectoris. The trial consisted of a 3-day washout: a 1-week period with verum or placebo patch followed by a second 1-week period with the other patch. During the study only sublingual NTG was allowed, and its consumption and the number of attacks recorded. Treadmill exercise tests were performed at the end of washout before patch application (baseline test) and 3 and 24 hours, respectively, after each period of 7 days of application of 1 patch daily.

Systolic blood pressure and heart rate did not vary significantly at rest in the 17 patients who completed the trial. Angina was reduced 31.3% and NTG consumption 34.3% ($p < 0.01$) during the week with Deponit® 10 as compared with placebo. Exercise duration increased 29 and 16.1% ($p < 0.001$ and $p < 0.1$, respectively) at 3 and 24 hours with a verum patch as compared with placebo. ST-segment depression at comparable loads decreased 69 and 40.5% ($p < 0.01$) at 3 and 24 hours, respectively, after application of Deponit. Onset of angina was delayed and maximal heart rate–blood pressure product significantly increased at 3 and 24 hours of treatment. It is concluded that Deponit 10 patch is effective in reducing anginal attacks and in increasing exercise capacity up to 24 hours after application.

(Am J Cardiol 1988;61:44E–51E)

The efficacy of nitroglycerin (NTG) for rapid relief of angina pectoris has long been known, but its role for the chronic management of ischemic heart disease has been limited by short duration of action, when administered sublingually and by extensive enterohepatic clearance when administered orally.

An alternative approach to prolong the action and to increase plasma levels of NTG has been transdermal delivery of NTG by ointment that is absorbed through the skin and, bypassing the gastrointestinal tract, avoids rapid first-pass metabolism within the liver.[1,2] The disadvantages of this method, consisting of several rather inconvenient applications and of variable plasma levels, have prompted research for other transdermal delivery systems in the form of discs or patches.[3]

Despite wide acceptance of these new devices[4] for treatment of both angina[5–8] and heart failure,[9–12] much controversy remains concerning efficacy, dosage requirements and duration of action of NTG.[13–27] Recent editorials have pointed out that, while a great number of short- and long-term studies have been performed, there is a need for large and well-controlled studies before firm conclusions can be drawn.[4,13,17]

In this study, which is a double-blind randomized placebo-controlled crossover trial, the antianginal efficacy of a new NTG delivery system (Deponit® 10, Schwarz GmbH) designed to release 10 mg of NTG within 24 hours, has been evaluated in patients with stable angina pectoris.

This new device has been extensively investigated by several workers[28–30] both in vitro and in vivo: plasma concentration reaches maximal levels 2 to 3 hours from application and a plateau is then maintained up to 24 hours.[28] The adhesive film of Deponit 10 has a surface area of 32 cm^2 and contains 32 mg of glyceryl trinitrate that is released at an average absorption rate of 10 mg/24 hours.

Methods

Nineteen men with stable exercise-induced angina, which was relieved by sublingual NTG, entered the study after giving written informed consent. Their ages ranged from 39 to 69 years (mean 53.0), body weight ranged from 62 to 84 kg (mean 71.0) and height ranged from 163 to 180 cm (mean 170.0). Each patient had 2 to 6 attacks of angina per week, relieved by rest or sublingual NTG, with unchanged pattern within 1 month preceding the study. Fourteen patients had had a myocardial infarction more than 3 months previously and a coronary angiogram showed multivessel disease in 10. Ischemic heart disease had been assessed by history and positive treadmill test results in all patients. All patients had been receiving long-term treatment with nitrates and were familiar with the treadmill technique for exercise testing at the time of enrollment. Five patients had normal results and 14 had abnormal results (presence of pathologic Q waves related to previous infarction) on electrocardiography.

Exclusion criteria were angina at rest or a changing pattern in the last month, recent myocardial infarction within 3 months, heart failure, left ventricular aneurism, large anterior infarction hindering evaluation of ST-segment during the test, atrioventricular or intraventricular conduction disturbances, left ventricular hypertrophy, ST-segment depression at rest, valvular heart disease, cardiomyopathy, complex arrhythmias at rest, serious disease of other organs or systems, need for digitalis, diuretics, calcium-antagonists, β blockers or antiarrhythmic drugs.

All patients who consented to the study were allowed to take NTG only and were requested to keep a diary of all anginal attacks and consumption of NTG tablets. If angina worsened at any time the patient was withdrawn from the study and was assigned to a more complex therapy.

Trial procedure: The study covers a period of 18 days (Fig. 1) and was a placebo controlled trial in a double-blind and randomized crossover design. After a 3-day washout period during which a placebo patch was applied every morning to a hairless part of the thorax and kept in place for 24 hours, on the fourth day each patient underwent a baseline treadmill test after heart rate and blood pressure were recorded in the supine and standing positions. After this time 0 test, medication-1-patch, which could be verum or placebo according to the randomization procedure, was applied. The same medication was applied at the same time for 7 days. On the seventh day (day 10) the patients performed a treadmill test 3 hours after the last application of medication-1-patch, after checking heart rate and blood pressure in the supine and standing positions. On the following day (day 2 from the start of the study), exactly 24 hours after the last application, after obtaining baseline data, another treadmill test was performed.

Immediately after recovery from this test the first medication-2-patch (crossover) was applied and so on for the next 6 days. On days 17 and 18, a treadmill test was performed at 3 and 24 hours after the last application of medication-2-patch, respectively. Heart rate and blood pressure at rest in the supine and upright positions were recorded before exercise testing on days 1, 4, 10, 11, 17 and 18 (Table I). Symptoms, adverse effects, compliance and adhesiveness of patches were checked ahead of each session.

Experimental procedure: Nineteen men, younger than age 70 years, with stable angina were admitted to the study. After a 3-day washout (9 patients were taking calcium antagonists, none were taking β blockers and 19 were taking nitrates). On the fourth day of the trial all patients underwent a baseline treadmill test according to the Bruce protocol. Exercise testing was performed in the morning in the fasting state.

Seventeen patients completed the trial undergoing a total of 5 tests (2 patients had to be withdrawn prema-

TABLE I Variations in Systolic Blood Pressure and Heart Rate at Rest in Supine and Standing Positions (n = 17)

Variable	Baseline	Deponit (3 hours)	Deponit (24 hours)	Placebo 1 (3 hours)	Placebo 1 (24 hours)
BP supine (mm Hg)	141 ± 14	140 ± 15	136 ± 12	136 ± 14	137 ± 12

turely for worsening of angina). Ten patients received the verum patch initially and then crossed over to the placebo patch; 9 received the placebo first. One patient from each arm of the trial was withdrawn prematurely before completing the trial.

Endpoints of exercise testing were exhaustion, angina of moderate severity, ST-segment depression ≥2 mm in any lead, dyspnea, failure of systolic blood pressure to increase within 2 stages, complex ventricular arrhythmias, systolic blood pressure >200 mm Hg or diastolic blood pressure >100 mm Hg, and symptoms or signs related to cerebral hypoxia.

One or more of the following criteria were used for a positive result: typical anginal pain of moderate severity, horizontal or downsloping ST-segment depression ≥1.5 mm, 0.08 second from the J point, and a decrease in blood pressure of 10 mm Hg or more.

A 9-lead electrocardiogram was recorded at rest, at the end of each treadmill stage and at every minute during a 10-minute recovery period. Three leads at a time were monitored continuously on a memory oscilloscope (D_1, D_2, D_3, aVR, aVL, aVF, V_2, V_4 and V_6). Blood pressure was recorded every minute by sphygmomanometer by the same operator. Heart rate was measured by electrocardiography. The laboratory temperature was between 23°C and 26°C and all patients were familiar with the treadmill system, having undergone at least another treadmill test previously.

The main criteria for evaluating efficacy of the drug in the trial were the number of anginal attacks and consumption of NTG capsules per week, exercise duration, time to onset of ST-segment depression, and time to onset of moderate angina.

Statistical analysis: The randomization process distributed patients in such a fashion that 10 patients initially received the drug and 9 the placebo in the first arm of the crossover. Because 1 patient from each group withdrew at the beginning of the trial, 9 patients receiving the drug first and 8 patients receiving the placebo initially completed the trial. Analysis of variance, Student *t* test and chi-square test were used depending on the variables considered to evaluate the differences between the 2 treatments.

Results

The trial was interrupted prematurely by 2 patients because of worsening of angina; subsequent outcome was benign in both cases. One patient had completed the baseline test and it was during the placebo week; the other patient had performed the baseline and the 3-hour test after receiving Deponit 10 at the end of the first week of trial.

Antianginal effect: In 17 patients (89.4%) who completed the study, a significant reduction of angina and NTG consumption was observed during treatment with Deponit 10 compared with placebo: Angina was reduced from 3.9 ± 1.7 attacks per week with placebo to 2.7 ± 1.6 (−31.3%) ($p < 0.01$) with treatment, and NTG capsule consumption diminished from 3.9 ± 2.4 to 2.6 ± 2.2 (−34.3%) ($p < 0.01$) (Fig. 2).

Effect at rest: Heart rate and systolic blood pressure both in the supine and standing positions did not show significant variation during treatment compared with placebo (Table I). Double product at rest (Fig. 3) did not change significantly as well and a small difference was observed between supine and standing positions (difference not significant).

Exercise testing: Table II lists exercise duration in each patient who completed the trial taking different medication and at baseline. Fourteen patients improved their endurance capacity at 3 hours taking Deponit 10 compared with placebo; one patient's condition worsened and 2 had no improvement. At 24 hours, a slight increase in duration was still present in 14 patients, no difference with placebo could be demonstrated in 2 and the condition of 1 patient was worse than with placebo.

Table III summarizes exercise duration, ST-segment depression at maximal and comparable loads, maximal pressure-rate product and change in reason for terminating the test. Because exercise duration coincided with time to onset of moderate angina in all patients but 1, only exercise duration is listed in the table. Exercise duration increased 29% ($p < 0.001$) and 16.1% at 3 and 24 hours, respectively, during treatment compared with baseline, whereas the increment was 26.2% ($p < 0.001$) and 15.3% ($p < 0.01$) compared with placebo (Fig. 4).

ST-segment depression at maximal load, i.e., end of exercise, was significantly different at baseline and with placebo, whereas ST depression at comparable exercise levels (Fig. 5) showed a significant difference both at baseline and with placebo. Three hours after administration of Deponit 10, a 66.6% reduction of ST-segment depression ($p < 0.01$) was demonstrated compared with baseline values and a 60% reduction compared with placebo after 3 hours ($p < 0.01$). At 24 hours a 41% reduction at baseline ($p < 0.01$) and a 30% reduction with placebo ($p < 0.05$) could be seen (Table III). Double product at maximal exercise did not significantly increase compared with placebo at 3 and 24 hours (6.7 and 4.1%, respectively), whereas a slight significance ($p < 0.05$) could be demonstrated at baseline (+8.1 and 7.8% at 3 and 24 hours, respectively, with Deponit) (Table III).

At baseline, all patients stopped exercising because of moderate angina, whereas 16 patients had angina as the endpoint during all subsequent tests. Only 1 patient became asymptomatic during all tests after the baseline. No patient had to terminate the test because of arrhythmias, heart failure or a decrease in blood pressure.

Time to ST-segment depression of 1 mm increased significantly compared with placebo only 3 hours after administration of Deponit (Fig. 6). Time for ST displacement to return to baseline decreased only slightly but not significantly during the 3- and 24-hour tests with Deponit compared with placebo and baseline (Fig. 7).

Adverse effects and adhesiveness of patches: The adhesiveness of patches was absolutely satisfactory because no detachment was noticed both by the patients and at control visits.

No accidents or complications occurred during the trial. Three patients complained of severe headache during the first days of treatment with verum patch

TABLE III Changes in Exercise Duration, ST-Segment Depression, Maximal Double Product and Causes for Termination of Exercise (n = 17)

compared with 1 patient during treatment with placebo. A slight skin erythema or local irritation was observed in 7 patients using the verum patch (36.8%) and in 1 patient taking placebo (5.2%).

Discussion

In this double-blind placebo-controlled crossover trial, a significant antianginal effect of a new transdermal NTG patch (Deponit 10) has been seen by more than a 30% reduction of anginal episodes and NTG consumption during the week of treatment compared with the week of placebo therapy. Despite the limitation that NTG plasma levels were not measured, the particular design of this study should not consider these results too subjectively and they should be discounted on that basis. This finding is in agreement with other investigators who reported reduction of anginal attacks during 2 to 3 weeks of treatment with transdermal NTG delivery systems.[3,5,22-25]

Moreover, objective means of quantifying the anti-ischemic effect of Deponit 10 is provided by a significant improvement of exercise endurance and delay of onset of angina during exercise both at 3 and 24 hours after patch application and by significant reduction of ST-segment depression at comparable exercise level. Time for regression of ST displacement was significant only at the 3-hour test, and double pressure-rate product presented only minimal changes at maximal exercise duration. To summarize, our data show an increase in exercise capacity with Deponit 10 and a significant anti-ischemic effect, which is more evident at 3 hours but still evident at 24 hours from the last application.

These observations are in agreement with most investigators who have demonstrated efficacy at 3 to 8 hours with transdermal NTG systems,[4,8,14,18,31] but antianginal and anti-ischemic efficacy at 24 hours is more difficult to demonstrate.[10,17,19,20,31] However, even among some of the negative trials, parameters other than total exercise duration, such as development of angina during exercise, time to ST-segment displacement of 1 mm and episodes of ST-segment displacement at Holter monitoring show significant improvement up to 24 hours.[14,15] On the basis of serial multigated radionuclide ventriculographic studies, hemodynamic improvement over 24 hours has recently been demonstrated in patients with angina pectoris.[10] In other studies, results that show improvement of

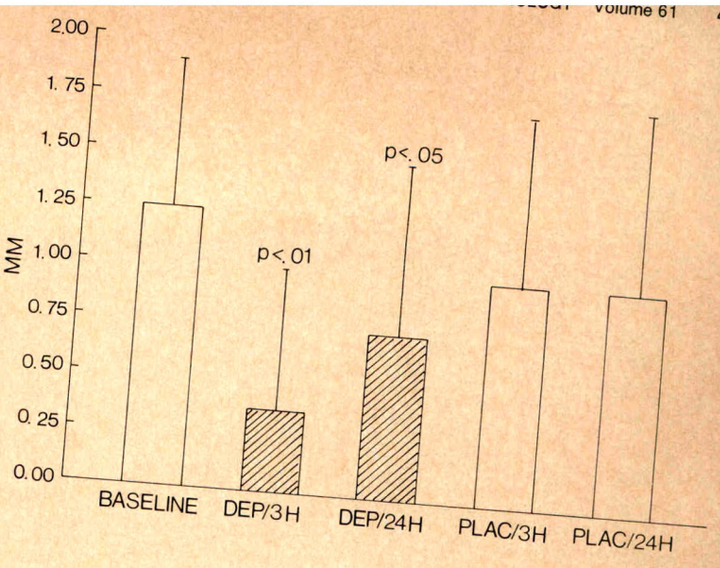

FIGURE 5. ST-segment depression under comparable load (difference with placebo (PLAC) is significant). DEP = Deponit.

some clinical significance fail to reach statistical significance probably because of a small number of patients in the trial.[7] Our data demonstrate a slight but significant effect present at 24 hours, which is in agreement with studies on other transdermal preparations.[3,5,10,21-23]

This study also demonstrated a lack of significant changes in heart rate and blood pressure at rest during treatment. This may have occurred because all of our patients had been receiving long-term therapy with nitrates when they entered the trial, which may have attenuated the decrease in systolic pressure and increase in heart rate as should be expected.[27,32,33] On the other hand, the relevance of this hemodynamic tolerance to the antianginal effect of transdermal NTG is the object of harsh debate.[34] Several investigators[7,8,15,16,18] have shown that increasing doses are required after exposure to oral or transdermal nitrate therapy, but many studies show a sustained effect despite treatment with transdermal NTG up to a period of 3 weeks.[5,14,18,22,24] The particular design of our trial, with a double-blind randomized sequence of placebo and verum patch, should have protected results from tolerance or "training" effects.

Finally, interpatient variability has been noted: Some patients presented a marked antianginal and anti-ischemic effect, some a slight effect, and others did not improve or did worse at exercise despite weak improvement of angina during the week of treatment with the verum patch. This observation is consistent with other studies in patients with angina or heart failure[4,7-11,28] and this range of responses may be explained on the basis of different absorption of transdermal NTG, resistance to NTG, cross tolerance with other nitrates, different response to the same dose of NTG in the individual patient, rapid tolerance developing in some patients, or different mechanism of action for each patient as pointed out by Scardi et al.[23] Ischemia may, in fact, be relieved by NTG from both a decrease in myocardial requirements for oxygen and an increase in oxygen supply. Accordingly, reduction of systolic arterial pressure or a decrease of venous pressure may occur as well as an increase of blood flow through dilatation of stenotic vessels or collaterals. In an individual patient, any 1 or all of these hemodynamic changes may take place. Patients whose conditions improve while taking low doses of NTG, according to Brown et al,[35] may be those in whom venodilatation and decreased preload is the major determinant of anti-ischemic effect, whereas patients who require higher doses may need more afterload reduction or coronary dilatation in order to improve. Identification of individual characteristics may become mandatory for optimization of nitrate therapy.

In conclusion, our findings appear to indicate that continuous transdermal NTG administration with Deponit 10 patches produces sustained antianginal and anti-ischemic benefits in most patients with stable angina pectoris. These benefits are considerably attenuated at 24 hours after the last application but are still present in some patients. Long-term tolerance and possible advantages over other transdermal NTG preparations have not been addressed in this work and need investigation in other long-term or comparative studies.

Acute and Chronic Efficacy of 10 mg of Nitroglycerin Patch in Stable Angina Pectoris

DŽENANA E. REZAKOVIĆ, MD, PhD, and JANEZ ŠTALEC

In a single-blind placebo-controlled study, acute and chronic efficacy and duration of action over 24 hours with a 10-mg nitroglycerin (NTG) patch was studied in 24 patients with stable angina pectoris. NTG patch effects were evaluated by means of a multistage treadmill exercise test. During the acute study, exercise tests were performed after the washout period, after placebo patch (5 hours postdosing) and NTG patch (5, 16, 20 and 24 hours postdosing); a 3-day washout period preceded each test. After 3 months of therapy with the NTG patch, exercise tests were performed in 3-day intervals of continuous therapy 5, 16, 20 and 24 hours after patch application. Then, after 7 days of placebo patch therapy, 1 exercise test was performed 5 hours after application. Statistics were obtained by multivariate analysis of difference. Placebo acute and chronic tests did not show any significant difference when compared. Acute and chronic NTG patch tests, (5 to 24 hours) showed significant improvement of maximal exercise time, the time to onset of 1.0 mm ST-depression and to onset of angina as well as maximal ST depression and ST depression 3 and 6 minutes after exercise testing compared with placebo. These effects were significant over 24 hours after acute or continuous therapy, although all values started to decrease after 16 hours, with a decrease of 10% during the acute and of 15% during the chronic period, compared with values at 5 hours. The efficacy was maintained during 3 months of chronic therapy, even with slightly greater magnitude compared with acute administration, mainly during the time of the first angina and 1.0 mm of ST depression. This study revealed exercise efficacy of significant magnitude and a 24-hour duration of action of a 10-mg NTG patch during single and 3-month administration in patients with stable angina pectoris.

(Am J Cardiol 1988;61:52E–58E)

Transdermal nitroglycerin (NTG) patch efficacy, especially during chronic therapy, and duration of action over 24 hours are the prerequisite characteristics for this formulation to be accepted for long-term therapy in patients with stable angina pectoris.

This study investigates the efficacy and duration of action of 10 mg of the NTG patch over a 24-hour period during acute and chronic administration.

Methods

Patients: Twenty-four men (average age 53.5 years) with chronic stable angina pectoris were included in the study. This group was selected according to criteria of the Food and Drug Administration from patients with stable exertional angina pectoris, reproducible during multistage treadmill exercise testing with horizontal or downsloping ST-segment depression of ≥2.0 mm and ≥80-ms duration after the J point in either lead V_5 or another chest lead, performed in the washout period.

All patients had angina pectoris for 18 to 96 months and ≥5 anginal attacks per week; no change in the severity or frequency of attacks in the preceding 3 months had been observed. The status of the disease was stable during the trial. All patients had good responsiveness of chest pain to sublingual NTG. The electrocardiogram at rest showed normal ST segment and sinus rhythm. No patient had had unstable angina pectoris or myocardial infarction within the preceding 6 months. The diagnosis of coronary artery disease had been confirmed by the documentation of acute myocardial infarction in 22 patients 18 to 60 months before the study, and in 18 patients by coronary angiography demonstrating significant luminal diameter narrowing

of at least 1 major coronary artery. Exclusion criteria were angina at rest or evidence of coronary artery spasm during angiography. No patient was treated for hypertension, chronic heart failure, severe renal or hepatic disease, atrioventricular or intraventricular conduction disturbances, Lown class III or IV ventricular arrhythmias, or severe diabetes or anemia. The study was performed on ambulatory patients who had given informed consent before entry. The study was approved by the hospital ethics committee.

Study design: The trial was a single-blind placebo-controlled study (Fig. 1). After being gradually withdrawn from previous therapy (within 7 days), patients performed 2 exercise tests to confirm ST-segment inclusion criteria (depression ≥2.0 mm) and to check that the reproducibility between the 2 tests did not vary more than 15%. Afterward, the trial began with a 3-day washout period, without any therapy apart from sublingual NTG capsules (0.8 mg) in case of anginal attacks; an exercise test was performed on the fourth day. Then, after a second 3-day washout period, 1 placebo patch was applied and an exercise test performed after 5 hours. Afterward, 3 washout periods of 3 days' duration were introduced. At the end of each period, a 32-cm^2 patch, releasing 10 mg of NTG was applied for 24 hours and an exercise test performed 5, 16, 20 and 24 hours after administration. After this acute period, 3 months of therapy was begun with 1 NTG patch (10 mg/24 hours). At the end of this period, 1 exercise test was performed 5, 16, 20 and 24 hours after dosing, with 3 days between each test and maintaining continuous patch therapy. This period was followed by 7 days of placebo patch therapy, administered in single-blind manner; an exercise test was performed 5 hours after patch application. Exercise tests were always performed in the morning.

No patient was taking any other drug except NTG (10 mg/24-hour patches) and sublingual NTG (0.8 mg of Deponit® and Perlinganit,® Schwarz GmbH) during the study. The patients were instructed to take off a previous patch and to apply a new one immediately at the scheduled time, without any nitrate-free interval. To perform morning exercise tests 16 and 20 hours after application, the patients had instructions for patch administration at a certain time to ensure a trial design during the acute test and to provide continuous patch therapy 3 days before testing during the chronic period. The patches were placed on a cleaned hairless part of the thorax. Sublingual NTG was always omitted on the morning of the exercise test, or if it was indispensable it was not given at least 1 hour before the exercise test. During 3 months of chronic therapy, the patients were examined monthly by a cardiologist and a resting electrocardiogram was recorded. Patients were required to report weekly by telephone for consultation with the medical staff.

NTG-capsule and patch counting with the marked date of application and continuous telephone and personal contact between the medical staff and the patients ensured high patient compliance and rigid adherence to the experimental protocol.

Experimental procedures: Each patient performed a multistage exercise test according to the Bruce protocol at the end of the washout phase and the placebo and NTG patch acute and chronic periods. Tests were performed on computer-assisted treadmill equipment (Viagraph-International Medical Corporation), with continuous data monitoring of heart rate, ST-segment changes and elapsed time during exercise and recovery period at the same time of the day and by the same staff. Patients were instructed to indicate time to onset of the first definite anginal pain and the time (maximal walking time) when the pain became of such severity—angina of "moderate severity" (maximal angina)—that the patient would ordinarily (or normally-usually) stop walking. Patients were instructed to

qualify the severity of the first angina and maximal angina, graded as 1 = weak, 2 = moderate, 3 = moderately severe, and 4 = severe. The lead V_5 was monitored on an oscilloscope and its ST segment was recorded throughout the test. Twelve-lead electrocardiograms were obtained at rest, at every 3-minute stage of the test and during a 3- and 6-minute recovery period, as well as at the onset of the first angina, 1.0 mm of ST depression and at angina of moderate severity. The time to onset of 1.0 mm of ST depression and maximal ST depression achieved during moderate angina and during maximal walking time were also recorded. ST-segment depression was also determined during maximal exercise time with placebo, (i.e., common exercise time).

The endpoints of the test were: typical angina of moderate severity, horizontal or downsloping ST-segment depression up to 3.5 mm in the lead in which the most prominent alterations occurred during preliminary testing (usually lead V_5), maximal predicted values of heart rate and walking time, marked dyspnea, no increase in systolic blood pressure in 2 consecutive stages, significant decrease of systolic blood pressure or heart rate, hypertensive reaction, subjective symptoms of cerebral hypoxia, life-threatening arrhythmias and physical exhaustion.

Blood pressure was recorded by sphygmomanometry at rest, at the end of each 3-minute stage of exercise, at onset of first definite angina and at angina of moderate severity, and at 1-minute intervals during a 6-minute recovery period.

All exercise test results were evaluated initally by the testing cardiologist and subsequently by another attending cardiologist who interpreted the tests in a blind manner.

Statistical analysis: Analysis of quantitative and qualitative differences between the washout period, and the periods of placebo or NTG patch acute and chronic therapy was performed by 1 of the multivariate analyses for repeated measurements, the model of differences based on the analysis of the matrix of differences.[1] In this analysis each subject serves as his or her own control. The differences were always calculated toward placebo values as a reference point. The variables used in multivariate analysis are presented in Table I. The significance of statistical analyses was determined at $p < 0.01$. Analyses were performed on the computer Univac 1100.

Results

Analysis of heart rate and blood pressure at rest showed that the NTG patch caused a significant decrease in systolic blood pressure in the first 5 hours (from 142.5 ± 3.6 to 128.8 ± 3.4 mm Hg, $p < 0.01$) and diastolic blood pressure at 5 and 16 hours after acute application (from 87.3 ± 2.6 to 77.1 ± 1.8 and 81.9 ± 1.9 mm Hg, respectively, $p < 0.01$). No change occurred during the other acute or chronic periods over 24 hours.

Exercise heart rate increased in all patients during the acute and chronic period, as well as the values of systolic blood pressure in all periods after the first 5 hours of patch application.

The results of multivariate analysis of exercise tests in the washout and acute or chronic placebo and NTG patch periods are listed in Table II.

Analysis of differences between placebo and washout period showed a significant improvement in maximal walking time (7%), the time to the onset of the first angina (16%) and to 1.0 mm of ST depression (9%) compared with washout values, with insignificant increase in maximal ST-segment depression (2%). Exercise test values obtained during the acute and chronic placebo periods did not differ significantly (Table II, Fig. 2 to 5).

Analysis of differences between results of NTG patch and placebo therapy demonstrated significant improvement of exercise values in all acute and chronic periods of NTG patch therapy compared with placebo. NTG patch treatment during acute and chronic administration demonstrated a significant prolongation in the maximal walking time, the time to onset of the first angina and 1.0 mm of ST depression, with a decrease in the maximal ST depression and ST depression 3 and 6 minutes after the end of exercise testing (Tables II to IV, Fig. 2 to 5).

Exercise improvement was significant after 5 to 24 hours of acute and chronic treatment; however, it was not constant at the same level. Values of the time to onset of the first angina and 1.0 mm of ST segment depression, as well as maximal walking time and ST depression worsened 16 to 24 hours after patch application in the acute phase (range 7 to 14%, mean 10%) and in the chronic period (range 7 to 21%, mean 15%) compared with 5-hour values of acute or chronic period. In contrast, these exercise values were better in the

chronic than in the acute period, at 5 hours (range 6 to 26%, mean 16%) and 24 hours (range 5 to 16%, mean 11%) compared with the acute phase (Table V).

Discussion

This study demonstrated significant improvement of antianginal and anti-ischemic exercise efficacy in the patients with stable angina pectoris during acute and chronic therapy with a 10-mg NTG patch—an increase in maximal walking time (range 44 to 34%) and a decrease in maximal ST-segment depression (range 47 to 36%)—over 24 hours compared chronic therapy with placebo. A significant increase in exercise heart rate and systolic blood pressure, during acute and chronic therapy, could be explained by an improvement in ventricular performance.

These results confirmed a sustained 24-hour duration of patch action during acute and chronic administration compared with placebo effect. However, all exercise parameters started to decrease 16 hours after application, so that 24-hour values significantly diminished compared with 5-hour results: average, 10 and 15% during the acute and the chronic periods, respectively. The decrease over 24 hours appears to be greater during the chronic than during the acute period. However, this did not essentially affect the results during the chronic period, because efficacy during continuous 3-month patch therapy was sustained, with even moderately greater magnitude in maximal walking time (by 6 to 5%), in maximal ST depression (by 14 to 8%), in the time to onset of the first angina (by 26 to 16%) and in time to 1.0 mm of ST depression (by 18 to 14%) compared with 5- and 24-hour acute values.

Placebo significantly affected some exercise test parameters, however, with worsening of values for maximal ST depression and ST depression at 3 and 6 minutes after the test; this exercise improvement was probably due to psychological reasons.

Much controversy exists about adequate NTG patch dosage in long-term therapy of angina pectoris; the dilemma being that low-dose (5 to 10 mg/24-hour NTG patch) is too low to ensure magnitude of efficacy, and the recommended high doses appear to induce rapid development of nitrate tolerance over 24-hours and during chronic therapy.

The review of world studies until the spring of 1987[2] showed that 28 publications of 10 mg/24-hour NTG patch acute and chronic exercise efficacy and 24-hour duration of action in 417 patients with stable angina pectoris have been published.

In the acute phase therapy, 11 studies with 197 patients demonstrated significant 10-mg NTG patch efficacy, with duration of action from 21 to 28 hours after administration. These studies had an average of 18 patients per study: in 4 placebo-controlled trials, performed in a double-blind manner (101 patients)[3-6]; in 3 placebo-controlled studies performed in a single-blind manner (46 patients)[7-9]; and in another 4 place-

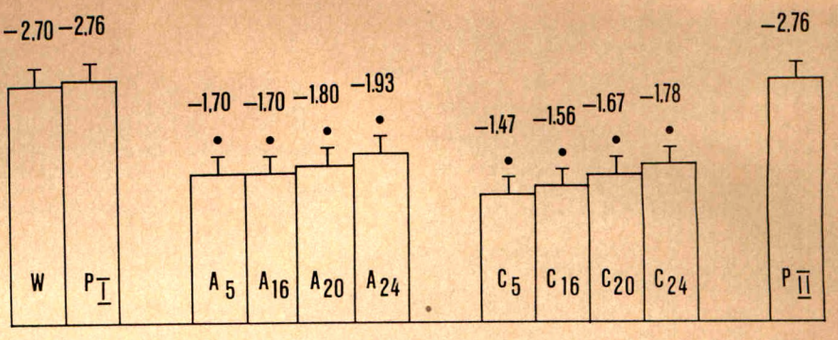

FIGURE 5. Maximal ST-segment depression (mm). Abbreviations as in Figure 2.

bo-controlled or open studies (50 patients).[10-13] However, 7 trials with 86 patients showed an attenuation in the efficacy after 2.5,[14-16] 4,[17,18] 6[19] or 10[20] hours of therapy. These studies (an average of 12 patients in each study) were all conducted in a placebo-controlled double-blind manner. Finally, 1 placebo-controlled double-blind study with 7 patients showed complete absence of efficacy over 24 hours.[21]

In the chronic phase therapy, 7 studies with 131 patients showed long-term (7 days to 12 months) 10 mg/24-hour NTG patch efficacy, with confirmed 24-hour duration of action. These studies had an average of 19 patients, with 2 trials conducted in a placebo-controlled double-blind manner (29 patients),[22,23] 3 in a placebo-controlled single-blind manner (44 patients),[8,24,25] and 2 other studies in a placebo-controlled or open manner (58 patients).[5,10] However, another 6 studies demonstrated either an efficacy only at 2 hours after therapy (1 study with 16 patients[26]) or negative chronic efficacy in any period over 24 hours of testing (5 studies with 74 patients[27-30]). These investigations had an average of 15 patients and all studies were conducted in a placebo-controlled double-blind manner.

Three studies continued acute investigations (78 patients) during chronic 10 mg/24-hour NTG patch therapy for 7 days, 21 days and 12 months, and confirmed that acute exercise effects over 24 hours were sustained during continuous treatment, with unchanged magnitude and duration of action.[5,8,10]

Additional findings of a placebo-controlled single blind comparative double-blind study (10 patients) demonstrated improved metoprolol efficacy with 10 mg/24-hour NTG patch in a 2-day trial.[31]

The results of these studies confirm that 10 mg/24-hour NTG patch therapy demonstrates significant improvement in exercise tolerance during single or continuous administration, with sustained chronic effects and duration of action over 24 hours in more than 50% of the patient population studied. The findings of our study support this conclusion. There is enough evidence that the dose of 10 mg/24-hour NTG patch is not too low and insufficient to produce exercise effects of significant magnitude and 24-hour duration of action during acute and long-term therapy.

However, the controversy still exists, because there are groups of patients with stable angina pectoris who have absence or rapid attenuation of efficacy taking this NTG dosage. Recently, in 2 placebo-controlled double-blind studies (22 patients), in which attenuation developed during continuous 10 mg/24-hour NTG patch therapy, nitrate-free intervals demonstrated that it could be prevented.[32,33]

TABLE V Significance of Tests Comparing Two Intervals*

Comparisons†	Mean Change (%)
$A_{24} < A_5$	10
$C_{24} < C_5$	15
$C_5 > A_5$	16
$C_{24} > A_{24}$	11

* Multivariate analysis of differences.
† $p < 0.01$.
A = acute; C = chronic; 5 and 24 = 5 and 24 hours.

The main problem for future investigations should be to define the reasons why some patients have significant beneficial effect while others demonstrate rapid nitrate tolerance or complete absence of efficacy with continuous low-dose NTG patch therapy.

Relation of Transdermal Nitroglycerin Efficacy with Dosage in Different Subsets of Patients

DŽENANA E. REZAKOVIĆ, MD, PhD

Two single-blind placebo-controlled studies were consecutively performed with nitroglycerin (NTG) (5 and 10 mg/24 hours) patches in 24 patients with stable angina pectoris. The relation of NTG patch efficacy with dosage and different subsets of patients during acute and chronic patch therapy was analyzed. NTG patch effects were assessed by multistage treadmill exercise test at 5, 16, 20 and 24 hours after patch application, during single patch administration and after 3 months of continuous therapy, with washout phases as well as with 1- and 7-day placebo patch periods. The analysis of differences between NTG and placebo patch demonstrated significant improvement of exercise capacity in the total group of 24 patients. A taxonomy analysis revealed 2 different subsets in the sample of 24 patients, having similar exercise ST depression but different exercise walking times in the washout period. Group I (15 patients), with an initial 68% of maximal predicted time, showed moderate increases in magnitude of exercise efficacy during the acute and chronic period, with low decrease of effects over 24 hours. Efficacy was greater during the chronic phase, with evident dose relation of all changes. Group II (9 patients), with 40% of maximal predicted time, demonstrated an increased efficacy during acute and chronic therapy, with a steep decrease of all values over 24 hours and significant improvement of exercise tolerance during chronic therapy; these changes were not mainly dose-related. These differences in the magnitude and in the pattern of exercise efficacy over 24 hours, during acute and chronic NTG patch therapy, could probably be attributed to different nitrate mechanisms of action, depending on the pathophysiologic characteristics of stable angina pectoris in 2 subsets of patients. The controversies about NTG patch efficacy have been discussed with regard to relation between multiple modes of nitrate action and the subsets of patients with different prevailing mechanisms of stable angina pectoris.

(Am J Cardiol 1988;61:59E–69E)

The controversies about transdermal nitroglycerin (NTG) efficacy are still unresolved. Studies of confirmed clinical efficacy during chronic therapy and of duration of action from 12 to 24 hours, as well as those with no evidence or insufficient effects in stable angina pectoris have been reported simultaneously. The questions about adequate NTG dosage and duration and magnitude of antianginal and anti-ischemic efficacy still wait for scientific answers.[1,2]

The analysis of the relation of NTG patch dosage and different clinical subsets of patients with the magnitude and the pattern of exercise efficacy, as well as with the duration of patch action in stable exertional angina pectoris was performed on the results of 2 studies. These trials were consecutively performed, first with 5 and then with 10 mg/24 hours of NTG during acute and chronic administration.[3,4]

Methods

Patients: Twenty-four men (average age 53.5 years) with stable angina pectoris (according to Food and Drug Administration classification) were included in the study. These patients were selected from a group with stable exertional angina pectoris reproducible during multistage exercise testing. They had horizontal or downsloping ST-segment depression of ≥2.0 mm and 80 ms in duration after the J point in either lead V_5 or another chest lead. Tests were performed in the washout period. The patients had ≥5 anginal attacks per week and all confirmed good responsiveness of chest pain to sublingual NTG. These patients had no change in severity or frequency of attacks in the preceding 3 months and the status of disease was stable during the trials. The electrocardiogram at rest showed normal ST segment. Angina pectoris had been present

from 18 to 96 months. No patient had unstable angina or myocardial infarction within the preceding 6 months. Ischemic heart disease had been confirmed in 22 patients, with acute myocardial infarction 18 to 60 months before the study, and in 20 patients with evidence of significant luminal diameter stenoses of at least 1 major coronary artery seen on coronary angiography. Exclusion criteria were angina at rest or evidence of coronary artery spasm during angiography. No patient was treated for hypertension, chronic heart failure, severe renal or hepatic disease, atrioventricular or intraventricular conduction disturbances, ventricular arrhythmias (Lown class III or IV), severe diabetes or anemia. The study was performed on ambulatory patients who had given informed consent before entry. The study was approved by the hospital ethics committee.

Study design: Two studies, each having an acute and chronic 3-month period, were consecutively performed in a single-blind placebo-controlled design in 24 patients with stable coronary heart disease. The first trial was performed with 5 mg/24-hour NTG patches and a second time with 10 mg/24-hour NTG patches.

After being gradually withdrawn from previous therapy (within 7 days), the patients performed 2 exercise tests to confirm ST-segment inclusion criterion (depression of ≥2.0 mm) and to check that the reproducibility between 2 tests did not vary more than 15%. Afterward, all patients had a 3-day washout period, without any therapy except sublingual NTG (0.8 mg) in case of anginal attack. Patients performed an exercise test on the fourth day. Then, after a second 3-day washout period, 1 placebo patch was applied and an exercise test performed after 5 hours. Afterward, acute testing with 5 mg/24-hour NTG patch at 5, 16, 20 and 24 hours after application was performed on 4 separate days, with a 3-day washout period preceding each NTG patch application. After this acute period, 3 months of therapy were introduced with one 5 mg/24-hour NTG patch each day. At the end of this phase, exercise testing was performed at 5, 16, 20 and 24 hours after administration on 4 separate days, with 3 days of continuous therapy between each test. This period was followed by 7 days of placebo patch therapy in a single-blind manner; an exercise test was performed 5 hours after patch administration at the end of this phase (Fig. 1). After this trial, the complete design was repeated, beginning with exercise testing after a 3-day washout period, followed by acute and chronic administration of 10 mg/24-hour NTG and placebo patches. Both trials were performed over 10 months for each patient.

During the study no patient was taking any other drug except NTG (5 and 10 mg/24-hour patches) and sublingual NTG (0.8 mg of Deponit® and Perlinganit®, Schwarz GmbH). A placebo patch was similar in size and form to the NTG patch. The patients were instructed to take off a previous patch and to apply a new one immediately at the scheduled time, without any nitrate-free interval. To perform 16- and 20-hour exercise tests during the morning, the patients had instructions for patch administration at a certain time, to ensure trial design during acute testing and to provide continuous patch therapy 3 days before testing during the chronic period. The patches were put on a cleaned and hairless part of the thorax. Sublingual NTG was always omitted on the morning of the exercise test, or if it was indispensable it was not given at least 1 hour before the exercise test. During each period of 3 months of chronic therapy, the patients were examined monthly by a cardiologist who recorded an electrocardiogram at rest. They were instructed to telephone weekly for consultation with the medical staff.

NTG-capsule and patch counting with marked date of application and continuous telephone and personal contact between the medical staff and the patients ensured high patient compliance and rigid adherence to the experimental protocol.

Experimental procedures: Each patient performed a multistage exercise test according to the Bruce protocol at the end of the washout phase, and the placebo and NTG patch acute and chronic periods. Tests were

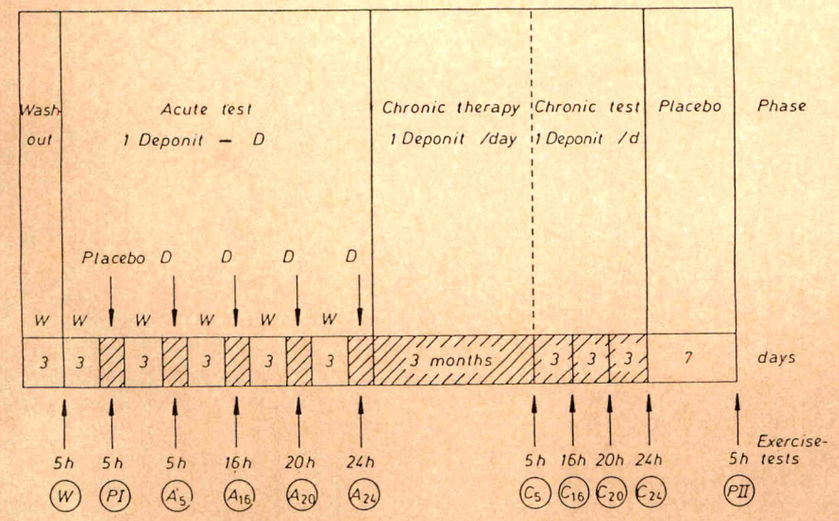

FIGURE 1. Trial design.

performed on computer-assisted treadmill equipment (Viagraph-International Medical Corporation), with continuous data monitoring of heart rate, ST-segment changes and elapsed time during exercise and recovery period, at the same time of the day and by the same staff. The patients had been instructed to indicate time to onset of the first definite angina and time (maximal walking time) when the pain became of such severity—angina of "moderate severity" (maximal angina)—that the patient would ordinarily stop walking. The patients were instructed to qualify the severity of the first and maximal angina, graded as 1-weak, 2-moderate, 3-moderately severe, and 4-severe. The lead V_5 was monitored on an oscilloscope and its ST segment was recorded throughout the test. The 12-lead electrocardiogram was obtained at rest, at every 3-minute stage of the test and during a 3- and 6-minute recovery period, as well as at the onset of angina, at the onset of 1.0 mm ST depression and when angina became of moderate severity. The time to onset of 1-mm of ST-segment depression and maximal ST depression during moderate angina and at maximal walking time were also recorded. ST-segment depression was also determined at placebo maximal exercise time (i.e., common maximal exercise time).

The endpoints of the test were typical angina of moderate severity, horizontal or downsloping ST-segment depression up to 3.5 mm in the lead in which the most prominent alterations occurred in preliminary tests (usually lead V_5), maximal predicted values of heart rate and walking time, marked dyspnea, no increase in systolic blood pressure in 2 consecutive stages, significant decrease of systolic blood pressure or heart rate, hypertensive reaction, subjective symptoms of cerebral hypoxia, life-threatening arrhythmias and physical exhaustion.

Blood pressure was recorded by sphygmomanometry at rest, at the end of each 3-minute stage of exercise, at onset of angina and during moderate angina and at 1-minute intervals during the 6-minute recovery period.

All exercise test results were evaluated initially by the testing cardiologist and subsequently by another attending cardiologist who interpreted the tests blindly.

Statistical analysis: Analysis of quantitative and qualitative differences between the washout period and the placebo or NTG patch acute and chronic periods of therapy was performed with one of the multivariate analysis for repeated measurements. The model of differences was based on the analysis of the matrix of differences.[3-5] The differences were always calculated toward placebo values as a reference point.

Testing of the hypothesis that a group of 24 patients had been constituted by different subsets of patients was performed by analysis of taxonomy[6] on 4 exercise test variables: time to the onset of angina and to the onset of 1 mm of ST depression, maximal walking time and maximal ST depression. The criteria of aggregation was the minimization of mean distance between the classes of variables. This analysis demonstrated the aggregation of the patients in 2 groups (1 group with 15 patients and 1 group with 9 patients) relating to washout values of these variables.

Analysis of differences between placebo and NTG patch values in previous 4 exercise variables for each of 2 groups of patients was performed again with the multivariate analysis of differences.

Analysis of differences in 4 exercise variables among 2 groups of patients for washout, placebo and NTG patch acute and chronic periods was performed with multivariate analysis of variance and discriminant analysis.[7]

The significance of statistical analysis was determined at $p < 0.01$. Analysis were performed on a Univac 1100 computer.

Results

The aim of analysis was to investigate the relation of NTG patch dose and potentially different subsets of patients with magnitude and pattern of exercise efficacy over 24 hours during acute and chronic administration.

The analysis of differences between the washout, placebo and NTG patch periods in all exercise test values (Table I) in the total group of 24 patients revealed a significant difference between placebo and 5, 16, 20 and 24 hours of NTG patch (5 and 10 mg) acute and chronic periods. These results were reported in 2 previous publications (Table II).[3,4] An insight to overall exercise test changes during NTG patch therapy compared with placebo is best demonstrated by Mahalanobis distances: the distance between placebo and each acute or chronic exercise test centroid, in multivariate analysis of difference (Fig. 2). Exercise test results during all periods with both NTG patch doses were signif-

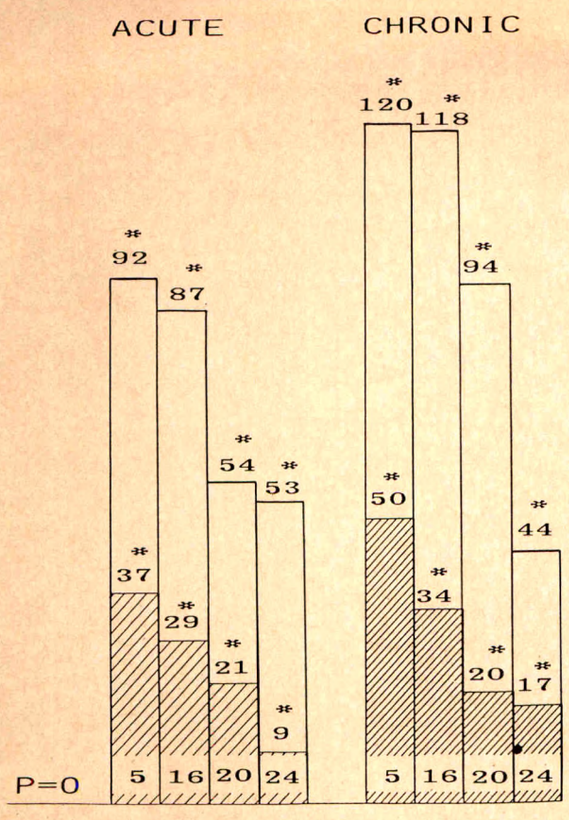

FIGURE 2. Mahalanobis distances of acute and chronic nitroglycerin patch exercise values from placebo centroid. P = placebo value; 5, 16, 20 and 24 = hours; *p <0.01 acute and chronic values (5, 16, 20 and 24 hours) compared with placebo; *shaded bars* = nitroglycerin 5 mg/24 hours; *open bars* = nitroglycerin 10 mg/24 hours.

icantly better than those with placebo. However, this improvement gradually diminished from 5 to 24 hours; results were poorer after 24 hours compared with results after 5 hours although still significant. It is obvious that exercise test results in all periods are better with 10 mg than with 5 mg of NTG. It is of interest to emphasize that exercise improvement was more sustained in the first 16 hours with the 10-mg NTG patch than with the 5-mg patch. The effects of the 5-mg patch started to decrease sharply 5 hours after administration.

A more detailed analysis of the dose relation and exercise improvement showed that the 10-mg NTG dose had better effects in all presented variables, especially in the time to onset of angina and 1 mm of ST depression. Furthermore, the difference between 5- and 24-hour values with both dosages was higher during the chronic period. However, the decrease in all values during 24-hour acute and chronic therapy, calculated as a percentage of 5-hour values, was greater with the 10-mg NTG patch (Table III).

Exercise values during chronic therapy with both NTG dosages were significantly better compared with those during the acute period. This improvement was mainly in a prolongation of the time to onset of angina and to onset of 1 mm of ST depression. However, the dose effect was not seen any more and the improvement was similar for both dosages (Table IV).

Testing the hypothesis of different subsets within the group of 24 patients was performed by taxonomy analysis showing an aggregation of patients in 2 groups, one with 15 and the other with 9 patients. This aggregation was formed relating to the following exercise variables: time to onset of angina and 1 mm of ST

depression, maximal walking time and maximal ST depression. Each of these groups showed significant improvement in the previous 4 exercise variables with 5 and 10 mg NTG patches, compared with placebo (Table V). The further analysis of the differences, by the multivariate analysis of variance and discriminant analysis between 2 groups, revealed that they significantly differed in several characteristics.

First, these groups were significantly different at initial washout exercise status, demonstrating that with similar maximal ST-segment depression, group II had a significantly shorter time to onset of angina, 1 mm of ST depression and maximal walking time (Tables VI and VII). In addition, 2 groups demonstrated significantly different magnitude and pattern of efficacy in all acute and chronic 5- or 10-mg patch periods.

Group I had moderate exercise improvement with both patch dosages, especially in the time to onset of angina and 1 mm of ST depression, with a relatively low percentage of decrease at 24 hours compared with 5-hour values. A decrease in values at 24 hours was slightly higher during the chronic phase than during the acute phase (Tables VI to VIII). The improvement during the chronic period was demonstrated only in the prolongation of the time to onset of angina and 1 mm of ST depression, compared with the acute phase (Table IX). The effect of the higher 10-mg dosage was obviously more important as seen with the magnitude of exercise improvement and in the greater decrease of values at 24 hours compared with the 5-mg dose during the acute and chronic periods. However, the dose relation was not evident in the magnitude of improvement during the chronic phase compared with the acute period; it was similar for both dosages (Tables VI to IX, Fig. 3 and 4).

Group II had similar decreases in maximal ST-segment depression, but much greater improvement in maximal walking time, and time to onset of angina and onset of 1 mm of ST depression with both patch dosages; there were steep decreases of all values over 24 hours during the acute and chronic periods, although they remained significant compared with values during placebo therapy. A difference between the values at 5 and 24 hours was similar to group I; it was slightly higher during the chronic phase than during the acute phase (Tables VI to VIII). Furthermore, this group had greater increase not only in the time to onset of angina and 1 mm of ST depression, but also in maximal walking time during the chronic period with both dosages compared with results during the acute period (Table IX). The dose relation was maintained only in greater exercise efficacy with the 10-mg patch therapy, whereas there was no longer any dose relation in the decrease during 24 hours in the acute and chronic periods and in the improvement of exercise time during the chronic period compared with the acute phase; values were similar for both dosages (Table VI to IX, Fig. 3 and 4).

When the groups were analyzed according to 24-hour duration of 15% increase in maximal walking time beyond washout values (which was the limit of prestated variability) 11 patients in group I who received the 5 mg patch achieved this magnitude of efficacy during the acute and chronic periods. Another 4 patients could not reach this value over 24 hours during the acute period. Two of them also did not reach it during the chronic period, whereas 2 patients achieved this limit during chronic therapy. Twelve patients had similar results with the 10-mg patch over 24 hours during the acute and chronic periods. Another 3 patients did not reach this limit during the acute period. Two of them also did not reach it during the chronic period, whereas 1 patient achieved this limit during chronic therapy.

In group II, prestated magnitude of efficacy was not achieved only by 2 of 9 patients with the 5-mg patch during the acute period, whereas all of them showed adequate response in the chronic phase. However all 9 patients with the 10-mg patch increased their maximal walking time to more than 15% during the acute and chronic periods.

Discussion

These results show that exercise improvement in the whole group of 24 patients achieved not only statistical significance, but also clinically important magnitude of efficacy during acute and chronic therapy in the prolongation of maximal walking time, the time to onset of angina and 1 mm of ST depression, with de-

creases in maximal ST depression with the 5- and 10-mg NTG patch.[3,4,8] These trials indicated significant 24-hour duration of action, but with a decrease in all values 16 hours after application, resulting in lower exercise values at 24 hours (7 to 14% and 7 to 21%) during the acute and chronic period with the 5- and 10-mg patch. All these changes were dose-related, since magnitude of exercise improvement and decrease of efficacy over 24 hours (higher during the chronic period than during the acute period) were greater with the 10-mg patch. Despite a decrease in values over 24 hours, improvement was greater during chronic 5- and 10-mg patch periods compared with acute values. The average percent increase during the chronic phase was 6% and 6% in maximal walking time; in maximal ST depression 9% and 11%; in time to onset of angina 23% and 21%; and in 1 mm of ST depression 19% and 16%, respectively, for each NTG dose. These changes were obviously dose-independent.

The analysis of 2 subsets of patients revealed that they were not homogeneous in all exercise parameters, although maximal ST-segment depression of ≥2.0 mm during the washout exercise test had been determined as inclusion criteria, to minimize variability and to achieve homogeneity of patients. ST depression was similar in the 2 groups, but maximal walking time and time to onset of angina and 1 mm of ST depression were significantly different; these findings indicate that they were essentially different in functional cardiovascular capacity. Since the groups were different at initial status, the differences in therapeutic response could be expected.

Group I patients had significantly higher maximal exercise time (mean 6.25 minutes to 7.14 METs, equal to 68% of maximal predicted walking time for 50- to 59-year-old men) as well as the time to onset of angina and 1 mm of ST depression. They responded with the 5- and 10-mg patch, with moderate augmentation of efficacy, greater for maximal ST depression (24 to 30%, 37 to 44%) than for maximal walking time (15 to 20%, 24 to 29%) during the acute and chronic periods. The magnitude of exercise decrease was low over 24 hours during the acute and chronic periods (mean 2 to 4% with the 5-mg dose and 7 to 10% with the 10-mg dose). Greater magnitude of efficacy and decrease over 24 hours during the acute and chronic periods were dose-related to the 10-mg patch. However, during chronic NTG patch therapy, limited improvement of exercise tolerance compared with the acute phase, was evident only in prolongation of the time to onset of angina (average 18 and 16%) and 1 mm of ST depression (average 16 and 11%) with 5- and 10-mg NTG being obviously dose-independent.

Group II patients had very low initial values in maximal walking time (mean 3.7 minutes, 5.14 METs equal to 40% of maximal predicted value) and time to onset of angina and 1 mm of ST depression. These patients responded (with 5 and 10 mg) with significantly greater magnitude of efficacy in maximal walking time (31 to 43%, 56 to 71%), whereas the change in maximal ST depression (17 to 23%, 34 to 41%) was similar in group I during the acute and chronic periods. The magnitude of exercise decreased markedly over 24 hours during the acute and chronic periods (mean 22 to 23% with 5-mg patch and 18 to 22% with 10-mg patch), with similar difference in percentage of decrease between acute and chronic periods as it was in group I. However, despite the marked decrease in

values over 24 hours, the increase in exercise tolerance during chronic therapy compared with the acute period was much higher than in group I, with prolongation of maximal walking time (average 11 and 10%) and improvement in time to onset of angina (average 38 and 33%) and 1 mm of ST depression (average 49 and 29%) with both doses. The augmentation of exercise values in this group evidently was only partly dose-related. However, major improvement in maximal walking time, time to onset of angina and 1 mm of ST depression, especially with augmented values during chronic therapy and marked decreases in all parameters over 24 hours. However, major improvement in maximal walking time, time to onset of angina and 1 mm of ST depression, especially with augmented values during chronic therapy and marked decrease in all parameters over 24 hours, may be caused by mechanisms independent of NTG dosage.

The characteristics of these 2 groups of patients define them as different responders with the NTG patch, with different magnitude of efficacy during acute and chronic therapy and different patterns of action over 24 hours and during chronic treatment. The response of group I was characterized by moderate magnitude of efficacy and low decrease of effects over 24 hours, evidently a dose-related phenomenon, whereas limited increase of efficacy during chronic therapy did not show this relation. There was a higher probability that values in group I patients could not reach more than 15% beyond washout values (the prestated value of variability) because of moderate magnitude of efficacy. In fact, 27 and 13% of patients with the 5-mg patch and 20 and 13% of patients with the 10-mg patch during acute and chronic therapy did not have these values over 24 hours. In contrast, group II showed important magnitude of efficacy, with a marked decrease of values over 24 hours and significant improvement of exercise tolerance during the chronic period, with clear evidence that these changes were not mainly NTG dose-dependent. There was an absence of a 24-hour duration of action in 22% of patients in group II only with the acute 5-mg patch, with confirmed efficacy during chronic therapy. All patients in this group reached the prestated limit of exercise variability during acute and chronic therapy with the 10-mg patch.

These differences in the magnitude and in the pattern of efficacy could probably be attributed mainly to different mechanisms of nitrate action, underlying their beneficial effects, which are likely to differ depending on the pathophysiologic characteristics of the patients with stable angina pectoris. These analyses revealed several parallel changes during nitrate therapy, an improvement of effort tolerance over 24 hours after single or continuous patch administration, a decrease of efficacy over 24 hours (of greater magnitude during chronic therapy), and finally the increase of efficacy during chronic therapy, compared with effects after single patch administration. The final magnitude of efficacy and duration of NTG patch action probably reflects as a resultant all these changes, depending on the mode of nitrate action, the prevailing mechanisms and the genesis of myocardial ischemia.

A study of 217 patients with confirmed coronary artery disease showed the complexity of responses to sublingual isosorbide dinitrate, with improvement of exercise tolerance in 43% of patients having the higher rate-pressure product and in 12% with reduction of rate-pressure product, while 18% of patients had no improvement.[9] These results support the view that nitrates exert their beneficial effects by different modes of action, an increase in coronary blood flow or a reduction of myocardial oxygen demand, depending on the underlying mechanisms of stable angina pectoris.

The patients in groups I and II significantly differed in initial exercise capacity; this finding indicates that they probably had different pathogenetic mechanisms responsible for their symptoms. The magnitude and the quality of NTG efficacy in group I appeared to be related to NTG dosage, whereas in group II, the magni-

tude and pattern of NTG effects were supposedly modified by the characteristics of patients themselves. No further investigations were performed to determine the prevailing mechanism of nitrate action. However, based on the differences in improvement of efficacy, especially with chronic therapy, group I probably had an increase in coronary reserve and group II a reduction in myocardial oxygen demand, although a certain degree of mixed action could not be excluded. Several studies have shown that chronic nitrate therapy in congestive heart failure was associated with a significant increase in effort tolerance, especially in submaximal exercise by a reduction of pulmonary capillary pressure and left ventricular pressures and by effects of repeated physical training.[10,11] Although the patients in our study did not have congestive heart failure, the exercise-induced elevation of left ventricular pressures could not be excluded in all patients, since they had severe stable angina pectoris. The improvement of the magnitude of exercise duration in group II patients—especially in submaximal levels seen as a major increase in time to onset of angina and 1 mm of ST depression as well as the independence of these changes to NTG dosage—support the assumption that it was due to preload reduction and to a decrease of myocardial oxygen demand.

Some contradictory results in NTG patch studies are probably the result of different subsets of patient samples included in the investigations. The review of all investigations of low-dose NTG patch (5 and 10 mg/24-hour) acute or chronic 24-hour exercise efficacy in patients with stable angina pectoris, performed in a placebo-controlled double-blind design, revealed altogether 26 publications with 431 patients until the spring of 1987.

Acute 24-hour investigations demonstrated in 7 studies of 151 patients (mean 22) exercise efficacy of 16

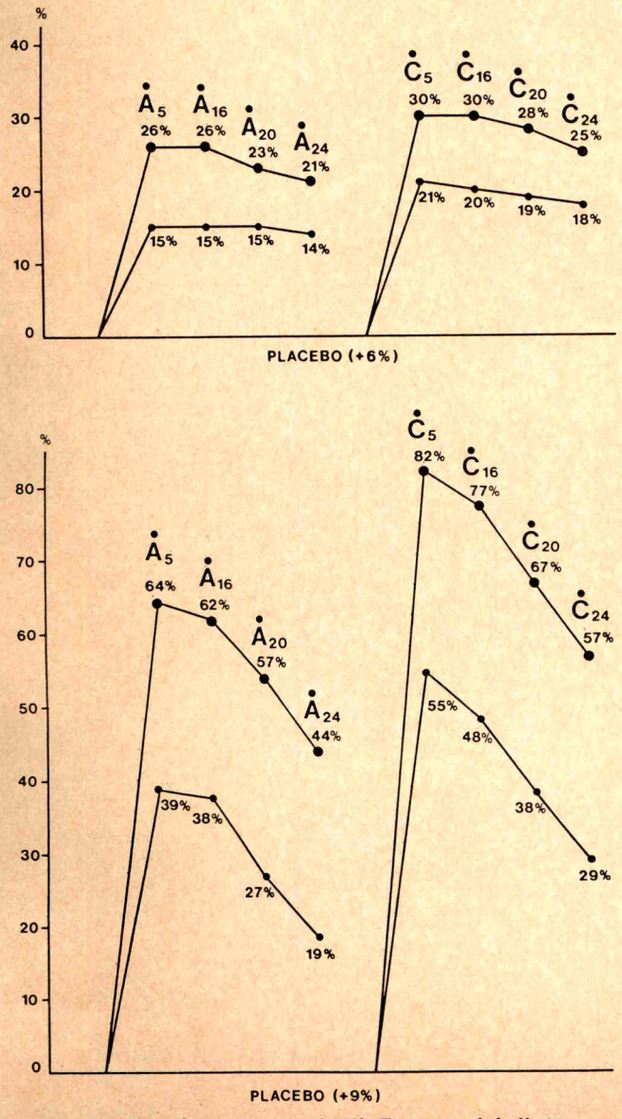

FIGURE 3. Maximal walking time (min). *Top*, group I; *bottom*, group II. *Small dots*, nitroglycerin (5 mg/24 hours). *Large dots*, nitroglycerin (10 mg/24 hours). to 24 hours' duration,[12-18] in 9 trials of 104 patients (mean 12) attenuation of efficacy at 2 to 3 hours,[19-22] 4 to 6 hours[23-26] and 10 hours[27] after patch application. One study of 7 patients revealed complete absence of any 24-hour effect.[28]

Chronic investigations confirmed in 4 studies of 79 patients (mean 20), positive exercise efficacy over 24 hours during 7, 14 and 17 days of continuous therapy.[13,29-31] Seven trials of 110 patients (mean 16) showed either an efficacy only at 2 hours after therapy (1 study)[37] or complete absence of any efficacy over 24 hours.[32-36]

One study of 40 patients, performed in placebo-controlled double-blind design during the acute period with positive exercise efficacy over 24 hours, was continued in an open trial and demonstrated sustained efficacy with a 24-hour duration of action during 12 months of continuous therapy with the 10 mg/24- hour NTG patch.[18]

This short review of trials of the same design, testing 24-hour duration of action and exercise efficacy with low doses (5 to 10 mg/24-hour patch) demonstrated contradictory results after single patch or chronic therapy. Placebo-controlled single-blind or open trials with the same NTG patch dosage showed the same discrepancies.[38]

Similarly, the analysis of some placebo-controlled double-blind randomized crossover studies, with 5 and 10 mg/24-hour NTG patch showing overall positive exercise efficacy after 7 to 14 days of continuous therapy, revealed that 58% of 40 and 57% of 52 patients achieved maximal exercise duration increase of more than 15% beyond the washout values (being the prestated variability).[39,40]

Any effort to compare or pool the results of different studies is complex and difficult, with many possibilities that may bias the conclusions of an entire population of patients,[41] but certain assumptions could be drawn from our and other cited trials.

There are supposedly multiple responses in the quality and quantity of NTG patch therapy among different samples of patients, as well as within 1 group of patients. It could be concluded that about half of the studied patients show statistically significant exercise improvement, with moderate to important clinical magnitude of efficacy, with sustained long-term effects and 24-hour duration of action with 5 to 10 mg/24-hour NTG patch therapy. The magnitude and pattern of action of these effects could be related to NTG dosage and to the characteristics of patients themselves; probably to the prevailing mechanisms of stable angina pectoris. However, there are patients without any evidence of NTG patch efficacy; in most studies it is not clear if this inefficacy is due to a failure to achieve therapeutic NTG blood levels with this method of NTG dosage, or if it is due to absence of NTG responsiveness. Finally, there are patients with attenuation of NTG patch efficacy (probably due to rapid development of nitrate tolerance) who could profit from intermittent dosing with nitrate-free intervals.[42,43]

It is not possible in a moment to define the conclusions about NTG patch efficacy, which could be generalized to the entire population of patients with stable angina pectoris. It is obviously necessary to titrate NTG patch dosage and regimen of therapy individually to each patient, taking into consideration the variety of potential NTG responses. Future trials should be designed to respond to the multiple, complex and contradictory phenomena occurring during NTG patch acute and chronic therapy. Finally, further investigations of NTG patch efficacy should define the homogeneous subsets of patients based on the prevailing mechanisms of cornary artery disease and assess its relation to the responses of NTG patch therapy.

Intravenous Isosorbide Dinitrate During Open-Heart Surgery and Its Role in the Treatment of Right-Sided Congestive Heart Failure.

R. SIMON PARSONS, MA, BM, BCh, FFARCS

Recent awareness of the importance of the functional integrity of the right ventricle and the effect of raised pulmonary vascular resistance on cardiac output after cardiopulmonary bypass has focused attention on means of protecting right ventricular myocardium and reducing right ventricular afterload during open-heart surgery.

A study of the acute effects of bolus intravenous isosorbide dinitrate (ISDN) has shown that after cardiopulmonary bypass, bolus intravenous ISDN produced highly significant ($p < 0.001$) decreases in mean pulmonary arterial pressure (13%), pulmonary vascular resistance (23%) and the ratio of pulmonary to systemic vascular resistance (20%), indicating that active pulmonary vasodilation had occurred in the absence of other hemodynamic changes. The results suggest that possibly the acute effect of low-dose ISDN after cardiopulmonary bypass is predominantly exerted on the right ventricular afterload if systemic arterial pressure is not elevated. Two different clinical situations are described in which intravenous ISDN proved beneficial, one being acute pulmonary hypertension after protamine sulphate and the second being acute right-sided congestive heart failure with systemic hypotension unresponsive to conventional therapeutic measures. Thus, ISDN may prove a useful agent for alleviating right ventricular dysfunction at a time of not infrequent cardiovascular instability, the period after bypass. (Am J Cardiol 1988;61:70E–73E)

During open-heart surgery, preservation of the functional integrity of the left ventricle has received widespread attention. However, right ventricular dysfunction in the perioperative period due to inadequate myocardial protection or other causes is being recognized more frequently and its importance accepted as a major cause of the limitation of cardiac output after cardiopulmonary bypass.[1,2] The addition of raised right ventricular afterload from pulmonary hypertension to the poor function of a damaged right ventricle may aggravate right ventricular dysfunction and can constitute a considerable therapeutic challenge.

Systemic vasodilator agents, when used to reduce pulmonary vascular resistance, may tend to produce systemic hypotension and consequently reduce coronary artery perfusion pressure.[3] Cardiac output may be reduced by systemic vasodilators in patients with a raised pulmonary vascular resistance. However oral isosorbide dinitrate (ISDN) has been reported to exert a favorable effect on pulmonary artery pressure and vascular resistance without producing undesirable severe systemic adverse effects.[4] A study of the effects of bolus injections of ISDN during open-heart surgery was performed to assess the acute effects of intravenous ISDN after cardiopulmonary bypass on the pulmonary and systemic circulations.[5] The results of this study encouraged the application of intravenous ISDN to the treatment of right-sided congestive heart failure (CHF) after cardiopulmonary bypass.

Use of Isosorbide Dinitrate by Bolus Injection

In a study of the effects of intravenous ISDN in 15 adult patients undergoing open heart surgery,[5] after standard premedication (lorazepam administered orally, followed by diamorphine and hyoscine administered intramuscularly), general anesthesia was induced and maintained with diazepam and fentanyl, with relaxation for intubation and ventilation with

100% oxygen to normocapnia provided by pancuronium and d-tubocurarine.

The response to ISDN before and after cardiopulmonary bypass was determined by various points of relative cardiovascular stability. Hemodynamic parameters and cardiac output were measured immediately before and at 3 to 5 minutes after an intravenous bolus of ISDN (0.25 to 0.3 mg).

Table I summarizes the acute effect of an intravenous bolus of ISDN (0.25 to 0.3 mg) on measured variables after cardiopulmonary bypass. After cardiopulmonary bypass, there were significant decreases in mean pulmonary artery pressure (13%) and in indexed pulmonary vascular resistance (23%), similar to results before bypass; however, there were no significant changes found in mean systemic artery pressure, indexed systemic vascular resistance or pulmonary capillary wedge pressure. The ratio of pulmonary to systemic vascular resistances was reduced by 20%. Right ventricular stroke work index was reduced by 15% in the absence of significant changes in cardiac index or right atrial pressure. Table II summarizes the analysis of the data after division into 2 groups according to the preexisting mean pulmonary artery pressure before administration of ISDN. In both groups, mean pulmonary artery pressure, indexed pulmonary vascular resistance and the pulmonary to systemic vascular resistance ratio decreased significantly and the percent changes were similar between the groups.

After this study, intravenous ISDN was administered when pulmonary hypertension had occurred or right-sided CHF had developed after cardiopulmonary bypass. An example of the first situation occurred after injection of protamine sulphate after cardiopulmonary bypass. The cardiovascular responses of 2 patients undergoing coronary artery revascularization, 1 of whom was receiving ISDN by constant intravenous infusion (2 mg/hour), were studied and the effect of ISDN on acute pulmonary hypertension was demonstrated. The cardiovascular responses of both patients, with an obvious systemic hypotensive episode commencing 15 seconds after the start of injection of protamine sulphate in the untreated patient, followed 15 seconds later by a prolonged pulmonary arterial hypertensive response that took more than 20 minutes to recover, are shown in Figure 1. In contrast, the patient treated with ISDN showed delayed and simultaneous systemic hypotensive and pulmonary hypertensive responses commencing 40 seconds after the start of protamine sulphate injection, the pulmonary hypertension being reduced by an additional bolus of ISDN (0.5 mg) (as shown) and returning to the original levels in approximately 3 minutes. The effect of intravenous ISDN on acute right-sided CHF in a patient undergoing coronary artery revascularization is shown in Figure 2. The systemic arterial blood pressure after cessation of cardiopulmonary bypass remained inadequate despite infusion of dobutamine and repeated injections of methoxamine. Right ventricular contraction was poor, the right ventricle dilated and right atrial pressure increased steadily as shown. After the failure to improve with inotropic support and methoxamine the patient received intravenous ISDN (0.3 mg) and within 30 seconds the right ventricular contraction improved, systemic arterial pressure then increased and right atrial pressure decreased. After another bolus dose of intravenous ISDN, the rate of infusion of dobutamine was reduced and the patient had an uneventful recovery.

TABLE I Values After Bypass Surgery in 15 Patients

	Before ISDN	After ISDN
MPAP (mm Hg)*	24.8 ± 2.5	21.6 ± 2.4
MAP (mm Hg)	69.7 ± 1.9	69.7 ± 2.0
HR (beats/min)	95.2 ± 3.3	95.0 ± 3.4
RA (mm Hg)	7.4 ± 0.6	7.3 ± 0.6
PCWP (mm Hg)	11.0 ± 0.7	10.6 ± 0.9
PVRI (dynes s/cm^5 m^2)*	397.9 ± 48.0	308.4 ± 43.6
SVRI (dynes s/cm^5 m^2)	1,963.9 ± 111.4	1,964.0 ± 123.4
CI (liters/min/m^2)	2.68 ± 0.1	2.71 ± 0.1
RVSWI (g · m/beat/m^2)†	7.5 ± 1.4	6.4 ± 1.6
LVSWI (g · m/beat/m^2)	23.1 ± 1.6	23.6 ± 1.7
PVRI/SVRI (%)*	23.3 ± 3.7	18.6 ± 3.3

*$p < 0.001$; † $p < 0.005$.

All values are expressed as mean ± standard error of the mean.

CI = indexed cardiac output; HR = heart rate; LVSWI = left ventricular stroke work index; MAP = mean systemic arterial pressure; MPAP = mean pulmonary artery pressure; PCWP = pulmonary capillary wedge pressure; PVRI = indexed pulmonary vascular resistance; PVRI/SVRI = ratio of pulmonary to systemic vascular resistance; RA = right atrial pressure; RVSWI = right ventricular stroke work index; SVRI = indexed systemic vascular resistance.

TABLE II Results Grouped According to Mean Pulmonary Artery Pressure

	Before ISDN	After ISDN
MPAP >25 mm Hg (n = 12)		
MPAP (mm Hg)	51.6 ± 6.5	45.7 ± 6.3
PVRI (dynes s/cm^5 m^2)	900.3 ± 113.2	724.6 ± 90.3
PVRI/SVRI (%)	51.6 ± 5.4	42.3 ± 4.7
MPAP <25 mm Hg (n = 32)		
MPAP (mm Hg)	16.7 ± 0.8	14.2 ± 0.7
PVRI (dynes s/cm^5 m^2)	251.3 ± 15.8	178.3 ± 13.7
PVRI/SVRI (%)	11.3 ± 0.8	8.5 ± 0.8

Values are expressed as mean ± standard error of the mean.

$p < 0.001$.

Abbreviations as in Table I.

Discussion

In the initial study,[5] the effects of intravenous ISDN were primarily on the right ventricle and pulmonary circulation, with no significant effects on the left ventricle and systemic circulation. In all cases, pulmonary vascular resistance decreased regardless of the level of pulmonary artery pressure. Furthermore, the decrease in pulmonary artery pressure and vascular resistance appeared unrelated to the preexisting pulmonary artery pressure. The lack of systemic effects may be related to the lack of systemic hypertension in these patients or may reflect the low dose of ISDN used in contrast with a previous study in which high-dose

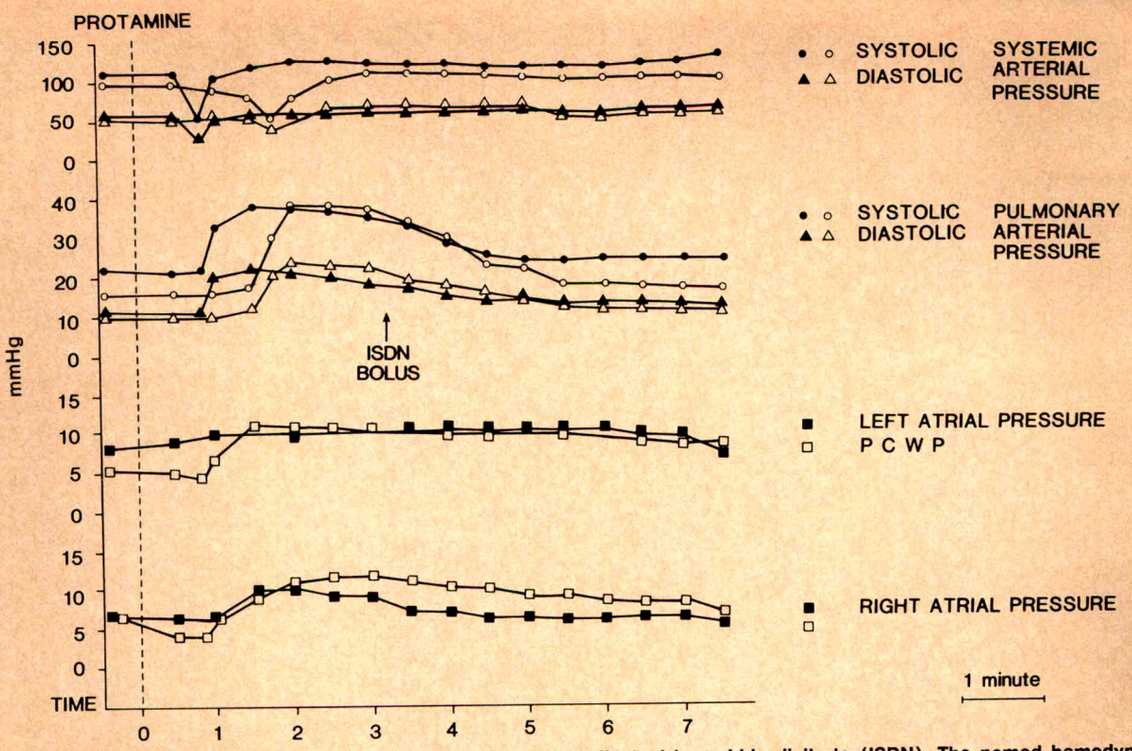

FIGURE 1. Hemodynamic responses to protamine sulphate and the effect of isosorbide dinitrate (ISDN). The named hemodynamic measurements for the patient treated with ISDN are shown with *open symbols* and those of the untreated patient with *closed symbols*. PCWP = pulmonary capillary wedge pressure.

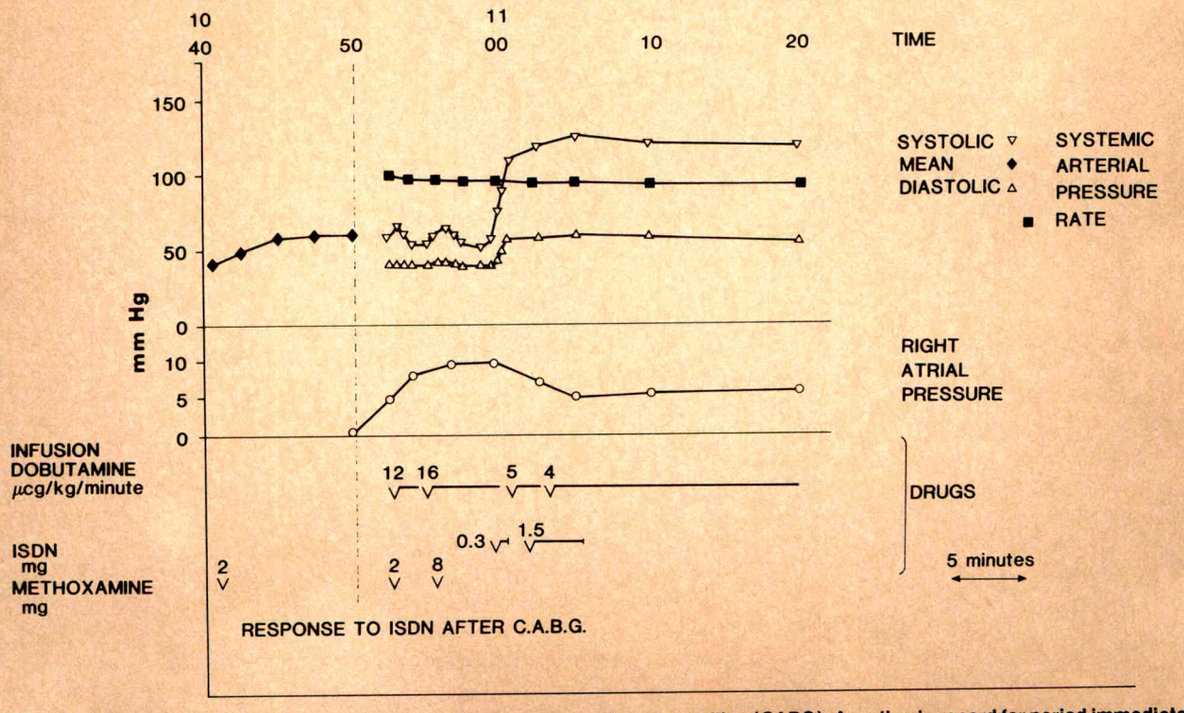

FIGURE 2. Response to isosorbide dinitrate (ISDN) after coronary artery bypass grafting (CABG). Anesthesia record for period immediately before and after cessation of coronary artery bypass grafting is indicated by a *dotted vertical line* at 1050 hours.

ISDN (up to 10 μg/kg/min) was used specifically for control of systemic hypertension.[6] Additionally, the reduction of pulmonary to systemic vascular resistance ratio indicated a predominantly pulmonary vasodilator effect.[7]

The reduction in right ventricular afterload in the apparent absence of systemic adverse effects suggests 2 possible roles for ISDN after cardiopulmonary bypass:

The first application may be in the management of pulmonary hypertension, which may be part of the original disease process or may follow the administration of protamine sulphate. Severe reactions to protamine sulphate are unusual but ISDN may attenuate an acute pulmonary hypertensive response without causing systemic hypotension. In addition, elevation of pulmonary vascular resistance that has been reported after cardiopulmonary bypass[8] in the absence of adverse reactions to protamine sulphate, may aggravate preexisting right ventricular dysfunction.

The second application may be found after severe right-sided CHF (Fig. 2). This reveals the paradox of a nitrate vasodilator being a good vasopressor by improving myocardial function. There may be many causes of right ventricular dysfunction,[1] which may be related to poorer myocardial protection of the right than the left ventricle during periods of aortic cross-clamping. Right ventricular failure may critically limit cardiac output even when a left ventricular mechanical assist device is in use.[9]

An agent that reduces right ventricular afterload and also improves coronary artery blood flow without reducing systemic arterial pressure would appear to be the appropriate treatment of right ventricular dysfunction. There may be a place for the prophylactic administration of ISDN from the period before bypass to achieve optimal biventricular performance and improve coronary arterial blood flow before and during a potentially highly stressful time for both ventricles, the early period after bypass.

Acknowledgment: I thank Philip B. Deverall for his kind permission to study the patients under his care and the laboratory technicians of the Department of Clinical Physiology for assistance with hemodynamic monitoring and blood gas analysis.

Effects of Long-Term Treatment with 120 mg of Sustained-Release Isosorbide Dinitrate and 60 mg of Sustained-Release Nifedipine on Myocardial Perfusion

BEATRICE STEGARU, MD, REINHARD LOOSE, MD, HELMUT KELLER, MD, JAN BUSS, MD, and EDUARD WETZEL, MD

Forty patients with coronary artery disease and scintigraphically proven myocardial ischemia were randomized into 2 groups receiving 4 weeks of treatment with either 120 mg of isosorbide dinitrate (ISDN) release or 60 mg of nifedipine release. Control exercise testing and myocardial scintigraphy were continued until anginal pains occurred, and repeated at identical individual workloads at the end of the 4 weeks of drug therapy. Myocardial scintigrams were evaluated by quantitative recording of counts in 60 segments/frame.

Twenty patients in the ISDN group (group I) exhibited 47 significantly ischemic areas. The remaining 20 patients (group II), treated with nifedipine, had 50 ischemic areas before therapy. In the ischemic areas in group I, there was a mean difference of 30.9% between counts at rest and during exercise in the pretreatment period, and a difference of 18.1% after therapy (39.0%). In group II, the pretreatment difference was 28.8%, decreasing to 20.6% after therapy (17.8%). Both groups of patients were subsequently subdivided into 3 subsets: (1) significantly improved perfusion, (2) significant worsening, and (3) unchanged myocardial perfusion. Group I had 59.5% of areas with significant improvement and 10.6% of areas with significant worsening. In 29.7% of the areas, the findings were unchanged. Group II had improvement in 40% of areas, of significantly worsened areas in 6%, and unchanged areas in 54%, in both groups myocardial ischemia was reduced by therapy, but ISDN improved myocardial perfusion to a considerably greater extent than did nifedipine.

(Am J Cardiol 1988;61:74E–77E)

The antianginal effects of isosorbide dinitrate (ISDN) and nifedipine were proven by a large number of studies published since the 1970s, demonstrating the increase in exercise capacity, reduction of frequency of angina as well as of ST-segment depression during exercise. A direct coronary dilating effect was demonstrated for both drugs. In addition, the hemodynamic effects of both drugs, consisting of preload by nitrates and afterload reduction by nifedipine, led to an improvement of myocardial perfusion.[1-3]

Methods

In this study, 40 patients with angiographically proved coronary artery disease were randomized into 2 groups of 20 each and treated for 4 weeks either with 120 mg of sustained-release ISDN or 60 mg of sustained-release nifedipine.

Before and after therapy, the weekly anginal frequency, ST-segment depression during exercise, double product (heart rate × blood pressure) during exercise and response of myocardial ischemia were analyzed. Individual maximal exercise to angina before treatment was repeated after 4 weeks of drug therapy and the results were compared. Myocardial scintigrams were recorded after a washout period before treatment and after 4 weeks of therapy with either drug, 1 hour after the last dose. The scintigrams were interpreted with the aid of a semiquantitative, computerized count analysis. Immediately after the exercise tests and after a 2-hour rest period, 3 scintigrams were recorded in the anterioposterior and 30° and 70° left anterior oblique projections. The data aquisition was performed with 600.000 counts/frame. The background was substracted with a linear interpolation in a circle (region of interest) using the modified algorithm

of Goris et al.[4] The noise reduction was obtained with a 2-dimensional 9-point Gauss filter. After selection of the center of the left ventricle determined by the operator, the radial transformation was performed with 60 sectors (6-degree steps) in counterclockwise direction, starting at 3 o'clock. The normalized circumferential profiles for all 6 projections (3 early and 3 late) were displayed on a color scope. A double projection of the profiles on a conventional pin-writer showed the ischemic regions with count-rate difference between exercise and rest and their localization.

The interpretation of the findings was simplified by assigning the ischemia inthe 3 projections to the anterior wall, the septum and the posterior wall of the left ventricle, respectively. The same areas were compared before and at the end of the drug therapy.

Clinical Features

The patient collective consisted of 31 men and 9 women (average age 56 years) equally distributed in the 2 groups. Coronary angiography in 34 of 40 patients showed 1-vessel disease in 6 patients, 2-vessel disease in 7 patients, 3-vessel disease in 19 patients and coronary artery spasm in 2 patients. Twenty-three patients had a history of coronary artery bypass grafting. Ninety-seven myocardial ischemic areas were found, 47 in group I and 50 in group II (Table I).

Results

In the 40 patients examined in this study, the clinical symptoms after treatment were highly significantly improved, as shown by the reduction in the frequency of angina per week and by the fact that the symptoms recorded at peak individual workload were no longer apparent at the same workloads at the end of the study. Results were similar in the exercise electrocardiogram in which the ST-segment changes at individually equal exercise levels no longer occurred (Tables II and III). In this respect, our results do not differ from the general well-known observations. There was no significant change in the double product of heart rate and blood pressure, although during nifedipine therapy, this value was, on average, increased because of tachycardia.

The scintigraphic study showed a decrease in myocardial ischemia, on average, with both drugs.

In the 97 ischemic areas there were different degrees of reduction or augmentation of ischemia (Fig. 1 and 2).

Statistical significances were calculated for each of the ischemic areas. The examined areas were subdivided in accordance with the treatment-induced change into (1) a group with significant improvement, (2) a group with significant worsening and (3) a group with unchanged findings, the latter comprising the statistically nonsignificant improvements and worsening, respectively.

A marked difference was found between both groups in favor of the ISDN-treated group, especially with regard to the number of areas with significantly reduced ischemia—28 (59.5%) vs 20 (40%), and with regard to the unchanged ischemic areas—14 (29.7%) vs 27 (54%)—during nifedipine therapy (Tables IV and V).

Discussion

Most of the studies interpreted by the usual qualitative assessment of the scintigraphic images showed a reduction in myocardial perfusion.[5] These reductions during treatment with both groups of drugs were never described. In our semiquantitative interpretation of ischemia by means of percent-count changes in the ischemic areas, it was possible to judge the scinti-

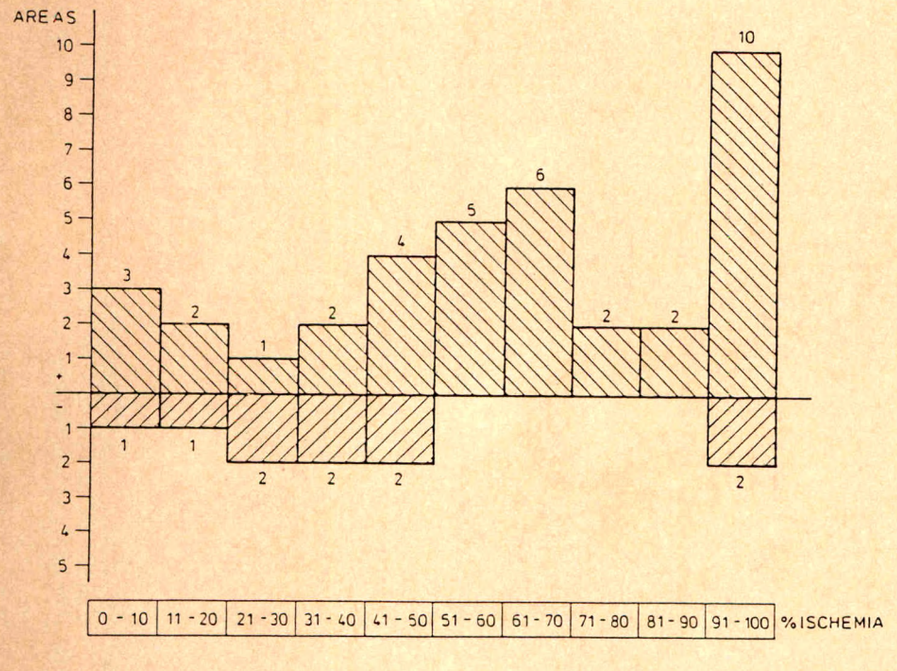

FIGURE 1. Percent ischemic changes of the 47 ischemic areas during therapy with isosorbide dinitrate.

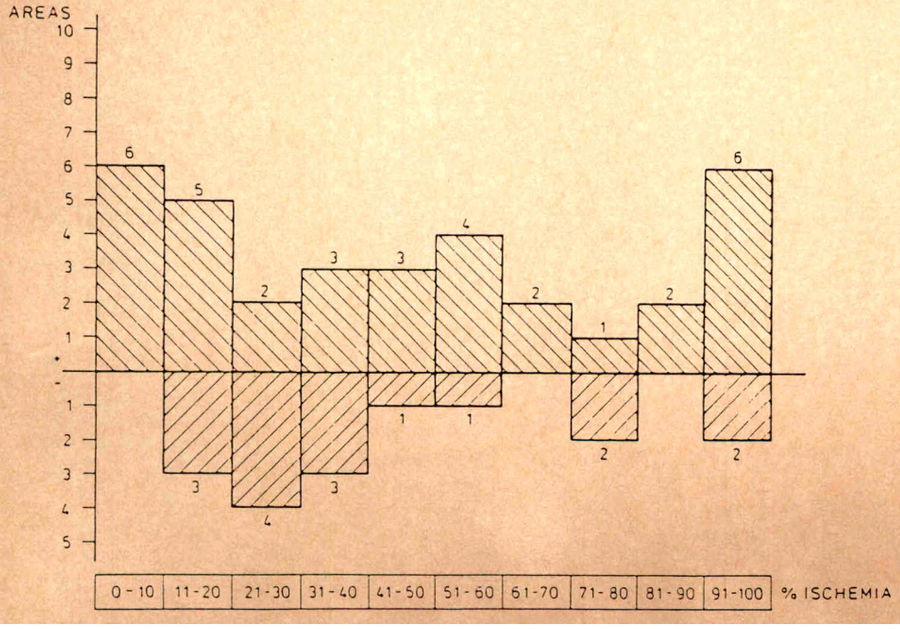

FIGURE 2. Percent ischemic changes of the 50 ischemic areas during therapy with nifedipine.

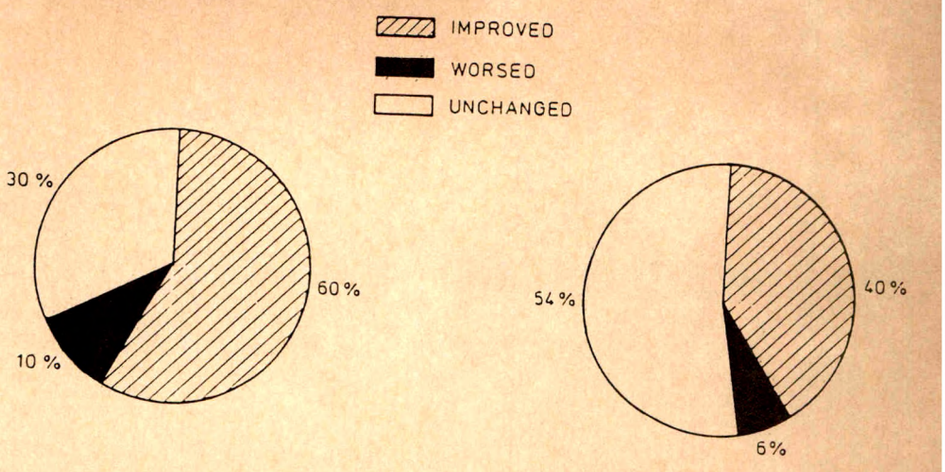

FIGURE 3. ***Left*****, changes in ischemic areas during therapy with isosorbide dinitrate.** ***Right*****, changes in ischemic areas during therapy with nifedipine.**

graphic images more objectively. The calculation of statistical significances for each of the ischemic areas, including a safety factor of 2 sigma, enabled us to assert a clear-cut improvement of worsening of myocardial perfusion after long-term therapy in images taken 1 hour after each drug. The comparison of computerized interpretations that showed significant changes with the usual qualitative interpretation of images was concordant. The statistically calculated nonsignificant reduction and augmentation summarized by us as unchanged findings, could also qualitatively be interpreted as irrelevant changes. In this group, there was a frequent tendency to overrate or underrate findings.

Even though there was a general significant reduction of ischemia in both groups, there was a marked difference in the extent of positive response in ischemic areas in favor of ISDN.

Contrary to the general clinical improvement, the reduction of ischemia was noted scintigraphically only in 60% of the areas during ISDN therapy and only in 40% of the areas during nifedipine therapy. A 90 to 100% disappearance of ischemia was found in 10 areas (22.2%) during ISDN therapy and in 6 areas (12%) during nifedipine therapy. The number of unchanged ischemic areas was 30% after ISDN administration vs 54% after nifedipine. The significant perfusion reduction in 5 areas (10.6%) during ISDN therapy and in 3 areas (6%) during nifedipine therapy can probably be explained by a redistribution of perfusion, or perhaps even by steal effects (Fig. 3). When the clinical relevance of symptomatic improvement was compared with the scintigraphic findings, one may ask whether the persistance of 30% of ischemic areas in group I and 54% of ischemic areas in group II could be interpreted as a change from symptomatic ischemia, recorded before treatment, into an asymptomatic silent ischemia. Holter electrocardiographic recordings showed that patients are unaware of about 80% of all ischemic episodes.[6,7] It is still not fully understood which factors are responsible for this phenomenon. There is still no answer as to whether antianginal therapy leads to an increased endorphin level.[7]

TABLE V Myocardial Ischemia Before and After Therapy with Nifedipine Release (60 mg/day)

* $p < 0.01$; † $p < 0.001$.

It should equally be decided whether thallium scintigraphy is perhaps overrated in this respect. However, this procedure appears to be far more sensitive and to yield earlier information on myocardial perfusion than the usual clinical investigative methods. The discovery of silent ischemia is a challenge for us to consider many new questions and aspects of the disease.

Effects of Isosorbide Dinitrates Intravenously in High Doses Over a Short Period in Anterior Acute Myocardial Infarction

SAMUEL SCLAROVSKY, MD, BORIS STRASBERG, MD, RUBEN F. LEWIN, MD, ALEX ARDITTI, MD, ELIEZER KLAINMAN, MD, and JACOB AGMON, MD

The effects of intravenous isosorbide dinitrate administered in high doses over a short period of time in 17 patients (14 men, 3 women, mean age 67 years) with anterior wall acute myocardial infarction were evaluated. Patients were classified into 2 groups based on the electrocardiographic pattern of acute ischemia. Patients presented with anterior acute myocardial infarction; an electrocardiographic pattern of third-degree ischemia demonstrated a more favorable electrocardiographic and radionuclear angiographic evolution than similar patients who presented with an electrocardiographic pattern of second-degree ischemia.

(Am J Cardiol 1988;61:78E–80E)

The recording of the electrocardiogram during progressive levels of ischemia shows several typical patterns (Fig. 1). The initial phase of ischemia is characterized by the development of a tall and peaked T wave (first-degree ischemia). If the ischemia progresses, then ST-segment elevation (second-degree ischemia) is observed in addition to the tall and peaked T wave. Finally, with maximal ischemia, a further elevation of the ST segment with disappearance of the S wave and an increment in the size of the R wave (third-degree ischemia) is seen.[1,2]

Patients with acute myocardial infarction (AMI) may demonstrate 1 of these 3 degrees of ischemia when admitted to the coronary care unit (if admitted before the development of pathologic Q waves). Each pattern of degree of ischemia has typical evolutionary changes when evolving to AMI (Fig. 2).

The purpose of this study is to evaluate the effects of intravenous isosorbide dinitrate given in high doses over a short period of time on the electrocardiographic (ECG) evolution of patients presenting during the early stages of AMI with initial ECG patterns of second- or third-degree ischemia (Fig. 1 and 2), and to compare the differences between both groups.

Methods

Inclusion criteria: Patients were admitted to the study when all the following criteria were met: (1) severe chest pain suggestive of AMI of less than 1 hour in duration; (2) an ECG pattern of second- or third-degree ischemia and without pathologic Q waves in the anterior chest leads; (3) no evidence or history of previous transmural (Q wave) anterior wall AMI; (4) a systolic blood pressure of ≥120 mm Hg; and (5) heart rate of no more than 90 beats/min.

Protocol of study: A 3-channel electrocardiogram with fixed precordial leads was recorded every 5 minutes during the first hours and every 15 minutes during the second hour. Radionuclear ventriculography was performed by the first-pass technique during the first 24 hours of admission and 14 days later. Administration of isosorbide dinitrate (50 mg dissolved in 50 ml of 5% dextrose) was started at 166 μg/min and was raised every minute until one of the endpoints was reached. No maximal dose was set. The endpoints of therapy were (1) a reduction in systolic blood pressure to 90 mm Hg, (2) an increment in heart rate >110 beats/min, and (3) a negativization of T waves in the precordial leads or completion of 2 hours of treatment.

Results

Patient characteristics: Seventeen consecutive patients with anterior wall AMI who fulfilled the inclusion criteria were included in the study. There were 14 men and 3 women (ages range from 55 to 74 years [mean 67]). Ten patients had second-grade ischem

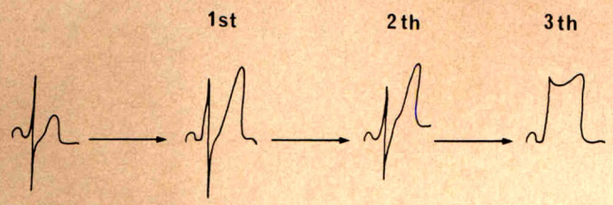

FIGURE 1. Schematic representation of degrees of ischemia. See text for explanation.

(group I), whereas 7 patients had third-degree ischemia (group II). The total dose of isosorbide dinitrate administered during the first hour was 90 ± 25 mg and during the second hour, 80 ± 30 mg.

Electrocardiographic characteristics and comparisons: *Q waves:* In group I, no significant Q waves were observed in the infarcted area within the first 2 hours from the onset of AMI. In group II, pathologic Q waves appeared in all 7 patients within 2 hours.

ST-segment elevation (Fig. 3): In group I, the initial mean level of ST elevation was 9 mm and decreased to

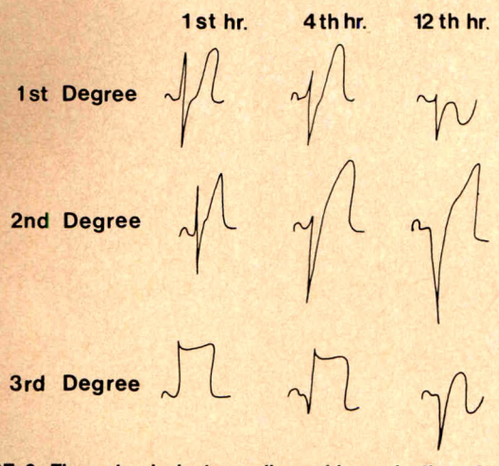

FIGURE 2. The natural electrocardiographic evaluation of acute anterior wall myocardial infarction according to the initial degree of ischemia.

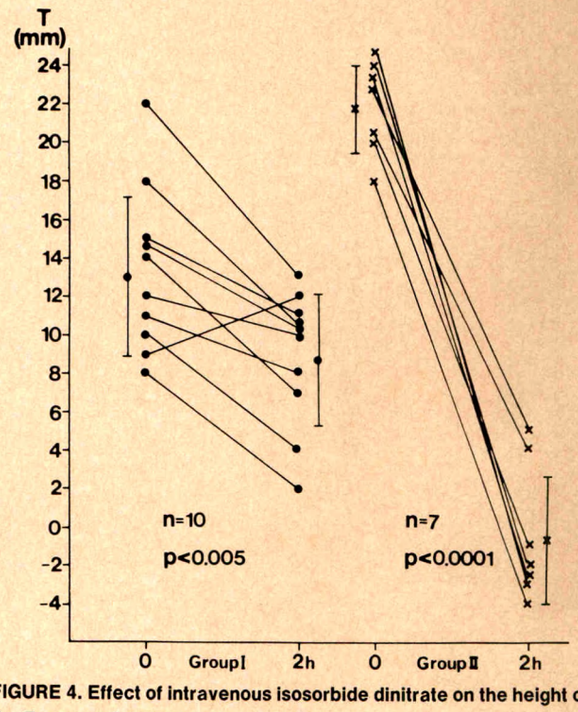

FIGURE 4. Effect of intravenous isosorbide dinitrate on the height of the T waves. See text for explanation.

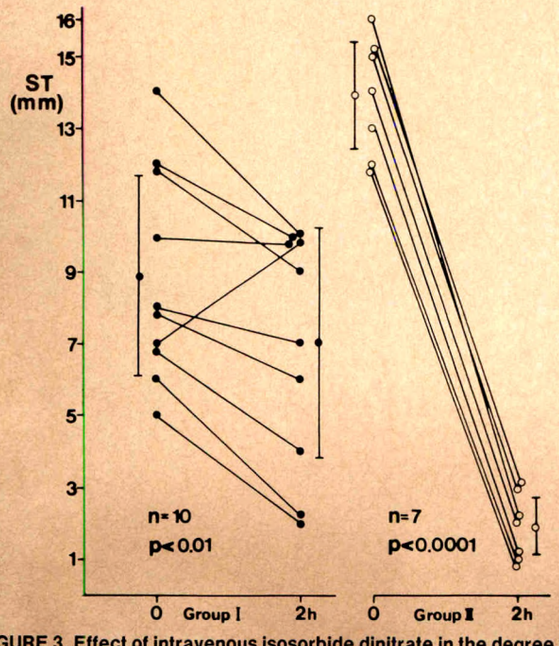

FIGURE 3. Effect of intravenous isosorbide dinitrate in the degree of ST-segment elevation. See text for explanation.

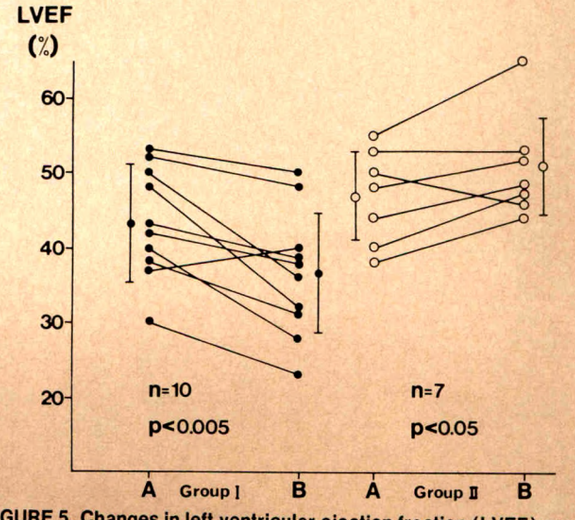

FIGURE 5. Changes in left ventricular ejection fraction (LVEF) over a 2-week period. See text for explanation.

a mean level of 7 mm after 2 hours of treatment ($p < 0.01$). In group II, the initial mean level of ST elevation was 14 mm and decreased to a mean level of 5 mm within 1 hour and to 2 mm within 2 hours of treatment ($p < 0.0001$). Significant differences were found between both groups for these 2 time points: $p < 0.005$ for the first hour and $p < 0.0005$ for the second hour.

T waves (*Fig. 4*): In group I, the initial mean level of the T wave was 13 mm. It remained unchanged after 1 hour of treatment and decreased to 9 mm after 1 hour ($p < 0.005$). In group II, the initial level was 22 mm and decreased to 10.5 mm after 1 hour, and to a negative level of −0.7 mm after 2 hours of treatment. Highly significant differences were observed between T-wave levels in both groups, $p < 0.0001$.

Radionuclear left ventricular ejection fraction (*Fig. 5*): Group I mean initial ejection fraction was 43% and decreased to a mean of 37% after 2 weeks ($p < 0.005$). Group II mean initial ejection fraction was 47% and increased to 53% after 2 weeks ($p < 0.05$). The initial ejection fraction for both groups was similar; however, the second study had statistical differences ($p < 0.005$).

Conclusion

Isosorbide dinitrate, when administered intravenously in high doses over a short period of time, has a beneficial effect on the ECG evolution of patients with anterior wall AMI, when the initial ECG pattern is third-degree ischemia. This treatment can be an alternative mode of therapy for patients with anterior AMI in whom thrombolytic therapy is contraindicated.

Age-Related Hemodynamic Effects of Intravenous Nitroglycerin for Acute Myocardial Infarction and Left Ventricular Failure

NICCOLO' MARCHIONNI, MD, ADAM SCHNEEWEISS, MD, MAURO DI BARI, MD, LUIGI FERRUCCI, MD, GUYA MOSCHI, MD, BERNARDO SALANI, MD, MARCO PAOLETTI, MD, COSTANZA BURGISSER, MD, and STEFANO FUMAGALLI, MD

Acute hemodynamic effects of intravenous nitroglycerin (NTG) were assessed in 24 patients with acute myocardial infarction and left ventricular failure, and results were compared between 2 groups of different age (group A—65 years or less, n = 12; group B—75 years or more, n = 12). Overall, hemodynamic effects of NTG consisted of an increase in stroke volume index and left ventricular stroke work index (+21 and +23%), coupled with a 16% reduction in systemic vascular resistance, and of a marked decrease in right atrial and pulmonary artery (PA) pressures. The hemodynamic end-point (5 to 10% reduction in mean systemic arterial pressure) used for NTG titration was achieved with a significantly lower dose in group B, in which a greater percent reduction in mean PA and mean PA wedge pressures was also observed. However, because effects of NTG on systemic vascular resistance were similar in groups A and B, it was concluded that the vasodilating action of NTG is maintained in advanced age, as opposed to what has been demonstrated for β-adrenergic agents.

(Am J Cardiol 1988;61:81E–83E)

In aged patients, mortality rates as high as 25 to 50% during acute myocardial infarction (AMI) have been reported,[1,2] and they have been most often attributed to a more frequent occurrence of left ventricular (LV) failure compared with younger patients.[3] Theoretically, the possibilities of a pharmacologic treatment of LV failure are greatly limited in aged patients, as it has been proved that the aging process in itself reduces the responsiveness of the myocardium to positive inotropic agents.[4,5] Vasodilators have been demonstrated to be a valid alternative to inotropic drugs in the treatment of LV failure secondary to AMI. Thus, it would be of interest to verify whether they retain their efficacy at any age. Whereas relaxation of the aorta by isoproterenol decreases with increasing age, such response caused by nitroglycerin (NTG) is not age-dependent in animals.[6]

This study, therefore, has been undertaken in humans to assess the hemodynamic effects of NTG in the elderly with LV failure during AMI and to compare results with those obtained in younger patients.

Methods

Patient selection: To compare groups with markedly dissimilar mean ages, subjects younger than 65 years and older than 75 years with transmural AMI and LV failure—defined as mean pulmonary artery (PA) wedge pressure higher than 15 mm Hg associated with LV stroke work index lower than 35 g·m/m^2—were selected. The following exclusion criteria were used: (1) sustained cardiac arrhythmias, (2) cardiogenic shock, and (3) pretreatment with any drug with known cardiovascular effects. Twenty-four patients were prospectively enrolled into the study: 12 (group A) were aged 65 years or less (mean 59, range 46 to 64), and 12 (group B) were older than 75 years (mean 79, range 75 to 90). The 2 groups did not differ in delay between onset of AMI and the study, prevalence of anterior vs inferior infarct location, and presence of a previous AMI.

Hemodynamic study: A Swan-Ganz catheter was advanced into the PA. A brachial artery was cannulat-

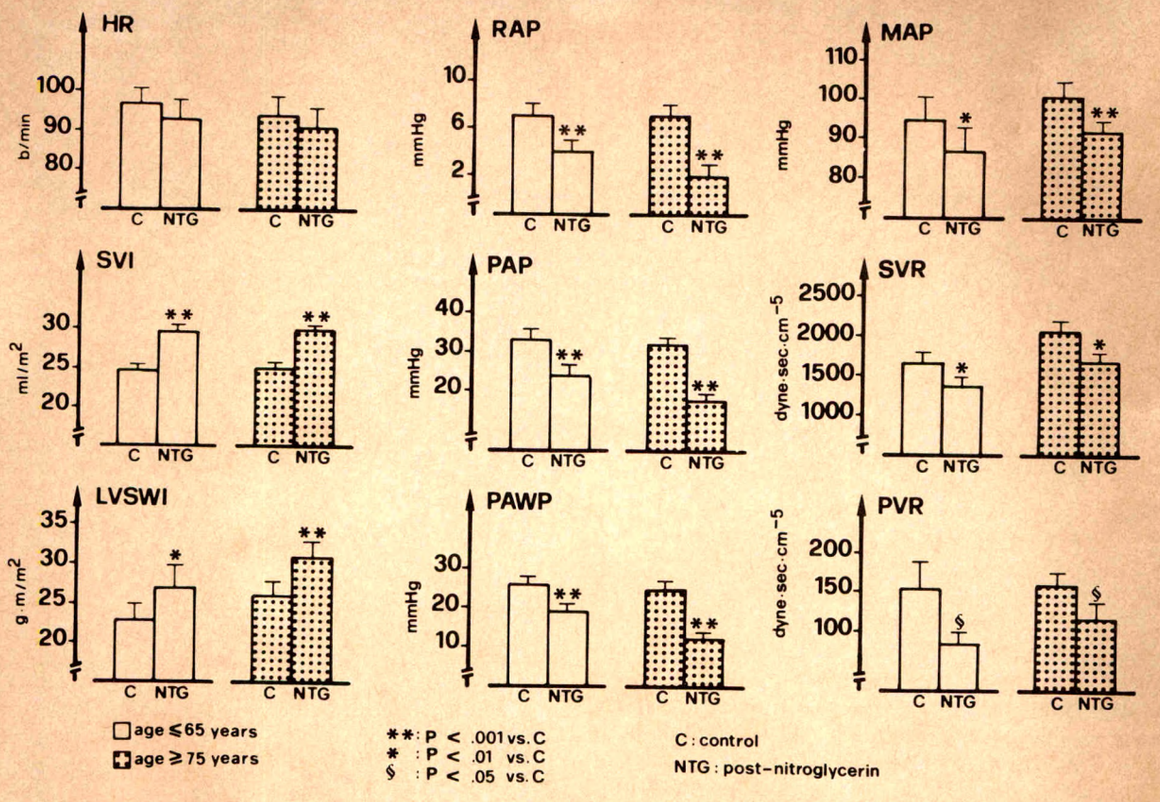

FIGURE 1. Hemodynamic effects of intravenous nitroglycerin (NTG) in young and elderly patients with acute myocardial infarction and left ventricular failure. Hemodynamics after NTG administration were assessed when mean systemic arterial pressure (MAP) was reduced to 5 to 10% of the control (C) value. HR = heart rate; LVSWI = LV stroke work index; PAP = mean PA pressure; PAWP = mean PA wedge pressure; PVR = pulmonary vascular resistance; RAP = mean right atrial pressure; SVI = stroke volume index; SVR = systemic vascular resistance.

ed as well. Pressures were referenced to the midaxillary line, with the patient in the supine position. Cardiac output was measured in triplicate by the thermodilution method. LV stroke work index was calculated as: SVI × (MAP − PAWP) × 0.0136, where SVI = stroke volume index (ml/m^2), MAP = mean systemic arterial pressure (mm Hg), and PAWP = mean PA wedge pressure (mm Hg). Systemic vascular resistance (SVR, dynes s cm^{-5}) and pulmonary vascular resistance (PVR) were calculated as: (MAP − RAP) × 80/CO; (PAP − PAWP) × 80/CO, where RAP = mean right atrial pressure (mm Hg), PAP = mean PA pressure (mm Hg) and CO = cardiac output (liters/min).

Protocol: After basal hemodynamic measurements, NTG was given intravenously by an electric infusion pump at an initial rate of 0.5 μg/kg/min. This dose was increased stepwise by 0.25 μg/kg/min at 5-minute intervals, until mean systemic arterial pressure was lowered 10% from the control level, an endpoint adopted in a previous study of NTG in patients with AMI[7]: at that moment, hemodynamics were reassessed, and time from start of NTG was recorded.

Statistical analysis: Significance of hemodynamic changes within the age groups was tested by 2-tailed *t* test for paired data; Student 2-tailed *t* test for unpaired data was used for comparing the data from the 2 age groups. Differences between percent frequencies were examined by the Fisher exact test. Data are expressed as mean ± standard error of the mean. A p value <0.05 was considered significant.

Results

Hemodynamic findings: A marked improvement after NTG infusion occurred in both groups (Fig. 1), as indicated by a relevant increase in stroke volume index and LV stroke work index, by a slight (−16%) but significant reduction in systemic vascular resistance and by a sharp decrease in right atrial and PA pressures. Reduction in mean systemic arterial pressure attained statistical significance in both groups, while heart rate was insignificantly reduced.

Comparison of the effects of nitroglycerin in groups A and B: Control hemodynamics were similar in the 2 groups. The selected hemodynamic endpoint was reached after a lower dose of NTG and in a shorter time in group B (0.7 ± 0.1 vs 1.7 ± 0.3 μg/kg/min, p <0.02; 17 ± 1 vs 33 ± 5 minutes, p <0.01). To ascertain whether some difference existed between young and elderly patients in their response to NTG, percent changes observed in group A and B were com-

pared (Table I). Changes in stroke volume index, LV stroke work index and systemic vascular resistance were almost identical in the 2 groups. Elderly patients showed a significantly greater reduction in mean PA and mean PA wedge pressures.

Mortality rates: Mortality rate was higher in group B than in group A (50 vs 17%), but such a difference did not attain statistical significance ($p = 0.09$). Two patients in group A and 3 in group B died from pulmonary edema. Three other elderly patients died from cardiogenic shock (n = 1) and from pulmonary thromboembolism (n = 2).

Discussion

Hemodynamic effects of intravenous NTG in patients with AMI with secondary LV failure are well established,[8] and consist of predominant venodilation associated with minor dilation of the arterial bed. Similarly, a marked reduction in right atrial, mean PA and mean PA wedge pressures (−70, −35 and −40%, respectively), coupled with a 16% decrease in systemic vascular resistance, was seen in all 24 patients.

Previous clinical trials[7,8] of NTG in AMI did not mention any comparison between young and elderly patients; moreover, an advanced age was considered as an exclusion criterion in some of those studies. In the present study, the same hemodynamic endpoint was achieved in group B, with a smaller amount of NTG than in group A. This may be the consequence either of increased sensitivity to NTG or of altered pharmacokinetics in the elderly. Because aging does not modify the in vitro sensitivity of aortic smooth muscle to NTG,[6] it is more likely that reduced metabolism was the reason for the lower effective dose in aged patients. This hypothesis is supported by a preclinical study[9] demonstrating a prolonged NTG half-life in older animals, secondary to reduced hepatic microsomal enzymatic activity.

The effects of NTG on venous return were more pronounced in elderly than in younger patients, as indicated by a more relevant reduction in right atrial and PA pressures. In our study (patients with similar changes in cardiac output, studied at rest in a recumbent, fixed position), venous return should depend only on venous tone and on the circulating blood volume. Thus, the reason for an age-dependent effect of NTG on parameters that are a function of venous return should either be a quantitatively different action on the venous vascular bed of young and elderly subjects or an age-related decrease in the circulating blood volume. Because NTG induced identical dilation in the portal veins of young and senescent animals,[6] the drug should have exerted similar effects on venous tone in groups A and B. An age-related decrease in extracellular fluids and in plasma volume have been indicated as a cause of the frequent untoward reactions to antihypertensive agents in the elderly.[10] Thus, a diminished plasma volume may have been the origin of the greater reduction in right atrial and PA pressures observed in group B than in group A.

TABLE I Percent Changes in Hemodynamic Parameters After Intravenous Nitroglycerin in Patients Aged 65 Years or Less (Group A) and 75 Years or More (Group B)

Variable (%)	Group A	Group B	p Value
HR	−4 ± 2	−3 ± 2	NS
SVI	22 ± 5	21 ± 5	NS
LVSWI	22 ± 6	25 ± 5	NS
MAP	−7 ± 2	−8 ± 2	NS
SVR	−16 ± 3	−16 ± 4	NS
RAP	−58 ± 7	−82 ± 11	NS
PAP	−28 ± 3	−42 ± 5	<0.02
PAWP	−29 ± 4	−51 ± 5	<0.005
PVR	−23 ± 10	−24 ± 11	NS

Abbreviations as in Figure 1.
NS = not significant.

However, we demonstrated that the vasodilating properties of NTG are preserved in elderly patients, in whom this drug is thereby a powerful aid in the treatment of LV failure secondary to AMI. In a recent randomized prospective trial,[7] NTG did not reduce immediate and 3-month mortality rates after AMI; similarly, despite relevant hemodynamic improvement, the prognosis of elderly patients in our study remained severe.

Further investigation is necessary to confirm age-dependent changes in NTG pharmacokinetics in humans. Nevertheless, since comparable hemodynamic effects were obtained after smaller amounts of NTG, the present study indicates that lower doses of NTG should be recommended in the elderly, in order to prevent excessive hypotension, particularly in patients with nearly normal pulmonary pressures.

IN CERTAIN DYSLIPIDEMIAS

A Desirable Balance of Efficacy

LOPID® *300 mg*
(gemfibrozil capsules, USP)

Lopid is indicated for treatment of adult patients with very high serum triglyceride levels in hyperlipoproteinemia other than type I who present a risk of pancreatitis and who do not respond adequately to diet.

© 1987 Warner-Lambert Company

with Patient Acceptance

Efficacy Lopid reduces synthesis[1-3] and increases clearance of triglyceride-rich VLDL.[2,3]

Patient acceptance Lopid has a very low order of side effects and has demonstrated limited effects on clinical and laboratory evaluations.[4]

Convenient BID dosage Two 300-mg capsules taken 30 minutes before morning and evening meals help ensure patient compliance.

Diet, exercise, and weight loss are the first choice in therapy of lipid disorders.

PARKE-DAVIS

Please see next page for references and a brief summary of prescribing information.

LOPID®
(gemfibrozil capsules, USP) 300 mg

Before prescribing, please see full prescribing information. A Brief Summary follows:

CLINICAL PHARMACOLOGY. LOPID is a lipid regulating agent which lowers elevated serum lipids primarily by decreasing serum triglyceride with a variable reduction in total serum cholesterol. These decreases occur primarily in the very low density lipoprotein (VLDL) fraction and less frequently in the low density lipoprotein (LDL) fraction. It has been reported that LOPID may increase levels of high density lipoprotein (HDL) subfractions, HDL_2 and HDL_3 as well as apolipoproteins AI and AII. Epidemiological studies have shown that both low HDL-cholesterol and high LDL-cholesterol are independent risk factors for coronary heart disease. It is not yet known whether pharmacological interventions designed to raise HDL-cholesterol alter morbidity or mortality due to coronary heart disease.

The mechanism of action has not been definitively established. In man, LOPID has been shown to inhibit peripheral lipolysis and to decrease the hepatic extraction of free fatty acids, thus reducing hepatic triglyceride production. LOPID inhibits synthesis and increases clearance of VLDL carrier apolipoprotein B, leading to a decrease in VLDL production.

Animal studies suggest that LOPID may, in addition to elevating HDL cholesterol, reduce incorporation of long-chain fatty acids into newly formed triglycerides, accelerate turnover and removal of cholesterol from the liver, and increase excretion of cholesterol in the feces.

LOPID is well absorbed from the gastrointestinal tract after oral administration. Peak plasma levels occur in one to two hours with a plasma half-life of 1.5 hours following multiple doses. Plasma levels appear proportional to dose and do not demonstrate accumulation across time following multiple doses.

LOPID mainly undergoes oxidation of a ring methyl group to successively form a hydroxymethyl and a carboxyl metabolite. Approximately seventy percent of the administered human dose is excreted in the urine, mostly as the glucuronide conjugate, with less than 2% excreted as unchanged gemfibrozil. Six percent of the dose is accounted for in the feces.

In a large, controlled multicenter trial of 427 patients, lipid and lipoprotein changes from average baseline (%) by hyperlipoproteinemic (HLP) type are summarized below for those patients receiving gemfibrozil, 1200 mg/day, at the end of 12 weeks.

HLP Type	TRIGLYCERIDE	CHOLESTEROL				RATIO: HDL Cholesterol / Total Cholesterol
		Total	VLDL	LDL	HDL	
IIa	−44%	−4.2%	−44.3%	−5.8%	+24.6%	+33%
IIb	−45%	−8.6%	−45.0%	−6.4%	+19.5%	+34%
IV	−40%	−1.8%	−40.8%	+14.6%	+17.4%	+23%

INDICATIONS AND USAGE. The initial treatment for hyperlipidemia is dietary therapy specific for the type of hyperlipoproteinemia. Drug therapy should not be used for the routine treatment of elevated blood lipids for the prevention of coronary heart disease. Excess body weight and excess alcoholic intake may be important factors in hypertriglyceridemia and should be addressed prior to any drug therapy. Physical exercise can be an important ancillary measure. Contributory diseases such as hypothyroidism or diabetes mellitus should be looked for and adequately treated. The use of drugs should be considered only when reasonable attempts have been made to obtain satisfactory results with nondrug methods. If the decision is to use drugs, the patient should be instructed that this does not reduce the importance of adhering to diet.

Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, and the adverse findings with clofibrate in two large clinical studies (see Warnings), use of gemfibrozil should be restricted to the following indications.

LOPID may be considered for the treatment of adult patients with very high serum triglyceride levels (type IV or type V hyperlipoproteinemia) who present a risk of abdominal pain and pancreatitis and who do not respond adequately to a determined dietary effort to control them. Patients with triglyceride levels in excess of 750 mg per deciliter are likely to present such risk. LOPID has little effect on elevated cholesterol levels in most subjects. A minority of subjects show a more pronounced response. Therefore, the physician should be very selective and confine gemfibrozil treatment to patients with clearly defined risk due to severe hypercholesterolemia (eg, individuals with familial hypercholesterolemia starting in childhood) who inadequately respond to appropriate diet and more effective cholesterol-lowering drugs.

LOPID is not useful for the hypertriglyceridemia of Type I hyperlipidemia.

The biochemical response to gemfibrozil is variable, and it is not always possible to predict from the lipoprotein type or other factors which patients will obtain favorable results. It is essential that lipid levels be assessed and that the drug be discontinued after three months in any patient in whom lipids do not show significant improvement.

The effect of gemfibrozil-induced reduction of serum cholesterol or triglyceride levels or elevation of HDL cholesterol levels on morbidity or mortality due to coronary heart disease has not been established. Several years may be required before ongoing long-term investigations will resolve this question.

CONTRAINDICATIONS. 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease. (See Warnings).

3. Hypersensitivity to gemfibrozil.

WARNINGS. 1. Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization, 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant 36% higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to noncardiovascular causes, including malignancy, postcholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

2. Long-Term Toxicity and Animal Tumorigenicity Studies – Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant (p greater than 0.05). There were no statistically significant differences from controls in the incidence of liver tumors in female rats, and in male and female mice.
